Angina Protection with Benefits for a Lifetime

ONCE-DAILY CONTROL WITH HEART-SAVING BENEFITS

By reducing heart rate and cardiac contractility, INDERAL LA helps protect the heart from the potentially serious and debilitating consequences of ischemia. A highly effective antianginal agent for around-the-clock control of symptoms, INDERAL LA also provides cardiovascular protection for a sense of security in the years ahead.

PROTECTION AND EXPERIENCE NO CALCIUM BLOCKER CAN MATCH

Unlike calcium blockers, INDERAL LA—either alone or with a nitrate—is recommended for early treatment of angina in the majority of patients. Equally important, INDERAL LA delivers the proven performance and safety profile of INDERAL tablets—confirmed by millions of patients during 16 years of clinical use.

START WITH 80 MG ONCE DAILY

Dosage may be increased to 160 mg once daily, as needed, to achieve optimal control. INDERAL LA should not be used in congestive heart failure, sinus bradycardia, cardiogenic shock, heart block greater than first degree, and bronchial asthma. Please see next page for further details and brief summary of prescribing information.

ONCE-DAILY **INDERAL® LA**
(PROPRANOLOL HCl) *LONG ACTING CAPSULES*

JUST ONCE EACH DAY FOR SIMPLIFIED CORE THERAPY IN ANGINA

ONCE-DAILY

INDERAL® LA

(PROPRANOLOL HCl) LONG ACTING CAPSULES

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)*

INDERAL® LA brand of propranolol hydrochloride **(Long Acting Capsules)**

DESCRIPTION. Inderal LA is formulated to provide a sustained release of propranolol hydrochloride. Inderal LA is available as 80 mg, 120 mg, and 160 mg capsules.

CLINICAL PHARMACOLOGY. INDERAL is a nonselective beta-adrenergic receptor blocking agent possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available receptor sites. When access to beta-receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

INDERAL LA Capsules (80, 120, and 160 mg) release propranolol HCl at a controlled and predictable rate. Peak blood levels following dosing with INDERAL LA occur at about 6 hours and the apparent plasma half-life is about 10 hours. When measured at steady state over a 24-hour period the areas under the propranolol plasma concentration-time curve (AUCs) for the capsules are approximately 60% to 65% of the AUCs for a comparable divided daily dose of INDERAL tablets. The lower AUCs for the capsules are due to greater hepatic metabolism of propranolol, resulting from the slower rate of absorption of propranolol. Over a twenty-four (24) hour period, blood levels are fairly constant for about twelve (12) hours then decline exponentially.

INDERAL LA should not be considered a simple mg for mg substitute for conventional propranolol and the blood levels achieved do not match (are lower than) those of two to four times daily dosing with the same dose. When changing to INDERAL LA from conventional propranolol, a possible need for retitration upwards should be considered especially to maintain effectiveness at the end of the dosing interval. In most clinical settings, however, such as hypertension or angina where there is little correlation between plasma levels and clinical effect, INDERAL LA has been therapeutically equivalent to the same mg dose of conventional INDERAL as assessed by 24-hour effects on blood pressure and on 24-hour exercise responses of heart rate, systolic pressure and rate pressure product. INDERAL LA can provide effective beta blockade for a 24-hour period.

The mechanism of the antihypertensive effect of INDERAL has not been established. Among the factors that may be involved in contributing to the antihypertensive action are (1) decreased cardiac output, (2) inhibition of renin release by the kidneys, and (3) diminution of tonic sympathetic nerve outflow from vasomotor centers in the brain. Although total peripheral resistance may increase initially, it readjusts to or below the pretreatment level with chronic use. Effects on plasma volume appear to be minor and somewhat variable. INDERAL has been shown to cause a small increase in serum potassium concentration when used in the treatment of hypertensive patients.

In angina pectoris, propranolol generally reduces the oxygen requirement of the heart at any given level of effort by blocking the catecholamine-induced increases in the heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. Propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure and systolic ejection period. The net physiologic effect of beta-adrenergic blockade is usually advantageous and is manifested during exercise by delayed onset of pain and increased work capacity.

In dosages greater than required for beta blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential. The significance of the membrane action in the treatment of arrhythmias is uncertain.

The mechanism of the antimigraine effect of propranolol has not been established. Beta-adrenergic receptors have been demonstrated in the platelets of the brain.

Beta receptor blockade can be useful in conditions in which, because of pathologic or functional changes, sympathetic activity is detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, greater than first degree, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

Propranolol is not significantly dialyzable.

INDICATIONS AND USAGE. Hypertension: INDERAL LA is indicated in the management of hypertension; it may be used alone or used in combination with other antihypertensive agents, particularly a thiazide diuretic. INDERAL LA is not indicated in the management of hypertensive emergencies.

Angina Pectoris Due to Coronary Atherosclerosis: INDERAL LA is indicated for the long-term management of patients with angina pectoris.

Migraine: INDERAL LA is indicated for the prophylaxis of common migraine headache. The efficacy of propranolol in the treatment of a migraine attack that has started has not been established and propranolol is not indicated for such use.

Hypertrophic Subaortic Stenosis: INDERAL LA is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL LA also improves exercise performance. The effectiveness of propranolol hydrochloride in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta-receptor stimulation. Clinical improvement may be temporary.

CONTRAINDICATIONS. INDERAL is contraindicated in 1) cardiogenic shock; 2) sinus bradycardia and greater than first degree block; 3) bronchial asthma; 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.

WARNINGS. CARDIAC FAILURE: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary, they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks, and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL (propranolol HCl), like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA: Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS: Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS. *General:* Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS. Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; thrombocytopenic purpura; arterial insufficiency, usually of the Raynaud type.

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.

DOSAGE AND ADMINISTRATION. INDERAL LA provides propranolol hydrochloride in a sustained-release capsule for administration once daily. If patients are switched from INDERAL tablets to INDERAL LA capsules, care should be taken to assure that the desired therapeutic effect is maintained. INDERAL LA should not be considered a simple mg for mg substitute for INDERAL. INDERAL LA has different kinetics and produces lower blood levels. Retitration may be necessary especially to maintain effectiveness at the end of the 24-hour dosing interval.

HYPERTENSION—*Dosage must be individualized.* The usual initial dosage is 80 mg INDERAL LA once daily, whether used alone or added to a diuretic. The dosage may be increased to 120 mg once daily or higher until adequate blood-pressure control is achieved. The usual maintenance dosage is 120 to 160 mg once daily. In some instances a dosage of 640 mg may be required. The time needed for full hypertensive response to a given dosage is variable and may range from a few days to several weeks.

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 80 mg INDERAL LA once daily, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg once daily. In angina pectoris, the value and safety of dosage exceeding 320 mg per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of a few weeks (see WARNINGS).

MIGRAINE—*Dosage must be individualized.* The initial oral dose is 80 mg INDERAL LA once daily. The usual effective dose range is 160-240 mg once daily. The dosage may be increased gradually to achieve optimum migraine prophylaxis. If a satisfactory response is not obtained within four to six weeks after reaching the maximum dose, INDERAL LA therapy should be discontinued. It may be advisable to withdraw the drug gradually over a period of several weeks.

HYPERTROPHIC SUBAORTIC STENOSIS—80-160 mg INDERAL LA once daily.

PEDIATRIC DOSAGE—At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

*The appearance of INDERAL LA capsules is a registered trademark of Ayerst Laboratories.

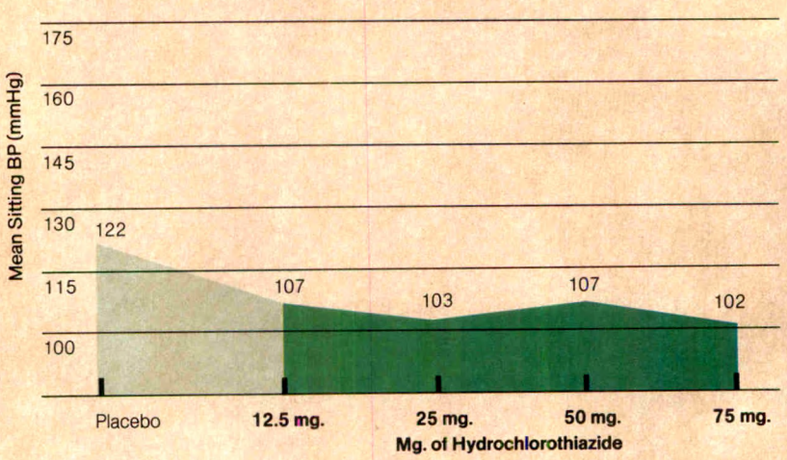
The Benefits of Less

Low doses of hydrochlorothiazide can provide most of the antihypertensive effect of larger doses.[1]

Increasing dosage above 25 mg. daily or improving bioavailability will not lead to increased antihypertensive efficacy in the majority of patients, but can result in a higher incidence of hypokalemia, hyperuricemia and hyperglycemia.[2]

HYDROCHLOROTHIAZIDE: FLAT DOSE-RESPONSE CURVE[3]



For the benefits of low dose diuretic therapy* with the added benefit of potassium-sparing triamterene

P R E S C R I B E

DYAZIDE®

25 mg Hydrochlorothiazide/**50 mg** Triamterene/SKF

*Not for initial therapy. See boxed warning.

3. Adapted from Beerman, B., and Groschinsky-Grind, M.: Antihypertensive Effect of Various Doses of Hydrochlorothiazide and Its Relation to the Plasma Level of the Drug, Eur. J. Clin. Pharmacol. 13: 195-201, 1978.

Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.

WARNING

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: The bioavailability of the hydrochlorothiazide component of 'Dyazide' is about 50% of the bioavailability of the single entity. Theoretically, a patient transferred from the single entities of Dyrenium (triamterene, SK&F CO.) and hydrochlorothiazide may show an increase in blood pressure or fluid retention. Similarly, it is also possible that the lesser hydrochlorothiazide bioavailability could lead to increased serum potassium levels. However, extensive clinical experience with 'Dyazide' suggests that these conditions have not been commonly observed in clinical practice. Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, 'Dyazide' should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on 'Dyazide' when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with 'Dyazide'. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with 'Dyazide', but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and 'Dyazide' should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. 'Dyazide' should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances; postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on 'Dyazide', although a causal relationship has not been established.

Supplied: 'Dyazide' is supplied as a red and white capsule, in bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

The finer art of pacemaking.

Introducing Genisis™

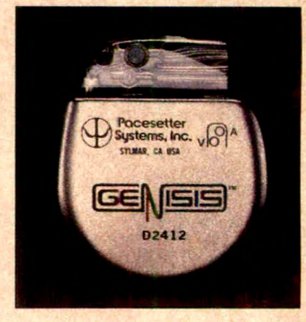
Dual chamber benefits with single chamber size and longevity.

Your patient's image in the mirror reflects the brand of pacemaker you choose. Choose the new Genisis pacemaker. The thinnest, lightest DDD yet.

Thinner profile and small size allow for a smaller incision. A smaller pocket. A comfortable fit. Although all patients will benefit from the small size and shape of Genisis, pediatric or thin patients having little subcutaneous tissue will especially appreciate its thin, *8 mm* profile and its light, *42 g* weight. Genisis also provides more years of service than thicker, less sophisticated DDD units.*

Choose the newest pacemaker design that meets your rigid demands and provides safe, effective pacing with no compromises. Genisis.

* Based on comparable output settings and conditions. *Data on file.*



Pacesetter® Systems, Inc.

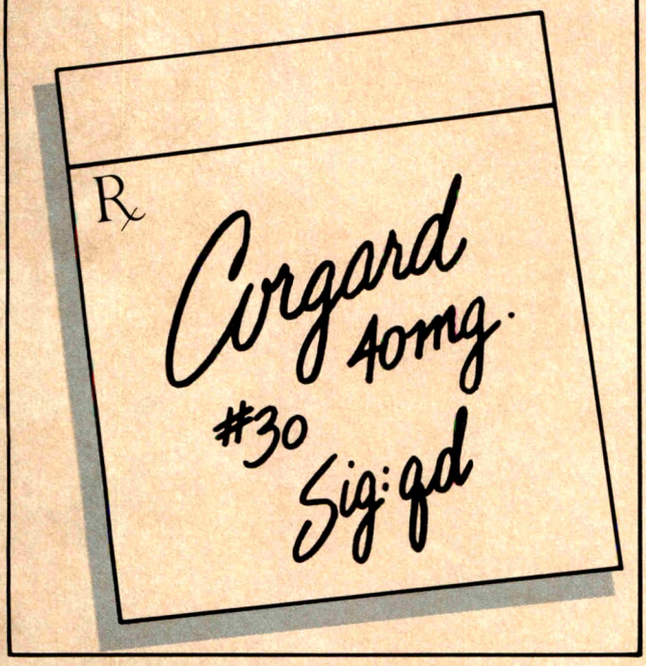
CORGARD®
(nadolol tablets)
R_x for Angina



CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure—Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery—Because beta-blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis—Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Renal Function—Use nadolol with caution (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients—Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign of impending failure. Advise patients in event of missed doses.

Drug Interactions—Concurrent administration may result in interactions with: Anesthetics, general—exaggeration of the hypotension induced by general anesthetics (see WARNINGS, Major Surgery). Antidiabetic drugs (oral agents and insulin)—hypoglycemia or hyperglycemia; adjust antidiabetic drug dosage accordingly (see WARNINGS, Diabetes and Hypoglycemia). Catecholamine-depleting drugs (e.g., reserpine)—additive effect; monitor closely for hypotension and/or excessive bradycardia.

Carcinogenesis, Mutagenesis, Impairment of Fertility—In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy—In animal reproduction studies with nadolol, evidence of embryo-and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus. Neonates of mothers who received nadolol at parturition have exhibited bradycardia, hypoglycemia and associated symptoms.

Nursing Mothers—Nadolol is excreted in human milk. Exercise caution when nadolol is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular—Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System**—Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory**—Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal**—Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous**—Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision; infrequent reversible alopecia. The following adverse reactions have been reported in patients taking nadolol and/or other beta-adrenergic blocking agents, but no causal relationship to nadolol has been established. **Central Nervous System**—reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal**—mesenteric arterial thrombosis; ischemic colitis; elevated liver enzymes. **Hematologic**—agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic**—fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous**—pemphigoid rash; hypertensive reaction in patients with pheochromocytoma; sleep disturbances; Peyronie's disease. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia—Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure—Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension—Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm—Administer a beta$_2$-stimulating agent and/or a theophylline derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; may be gradually increased in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 40 or 80 mg q.d. (doses up to 160 or 240 mg daily may be needed). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 40 or 80 mg q.d. (doses up to 240 or 320 mg daily may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100 and 1000 tablets and in Unimatic® unit-dose packs of 100 tablets.

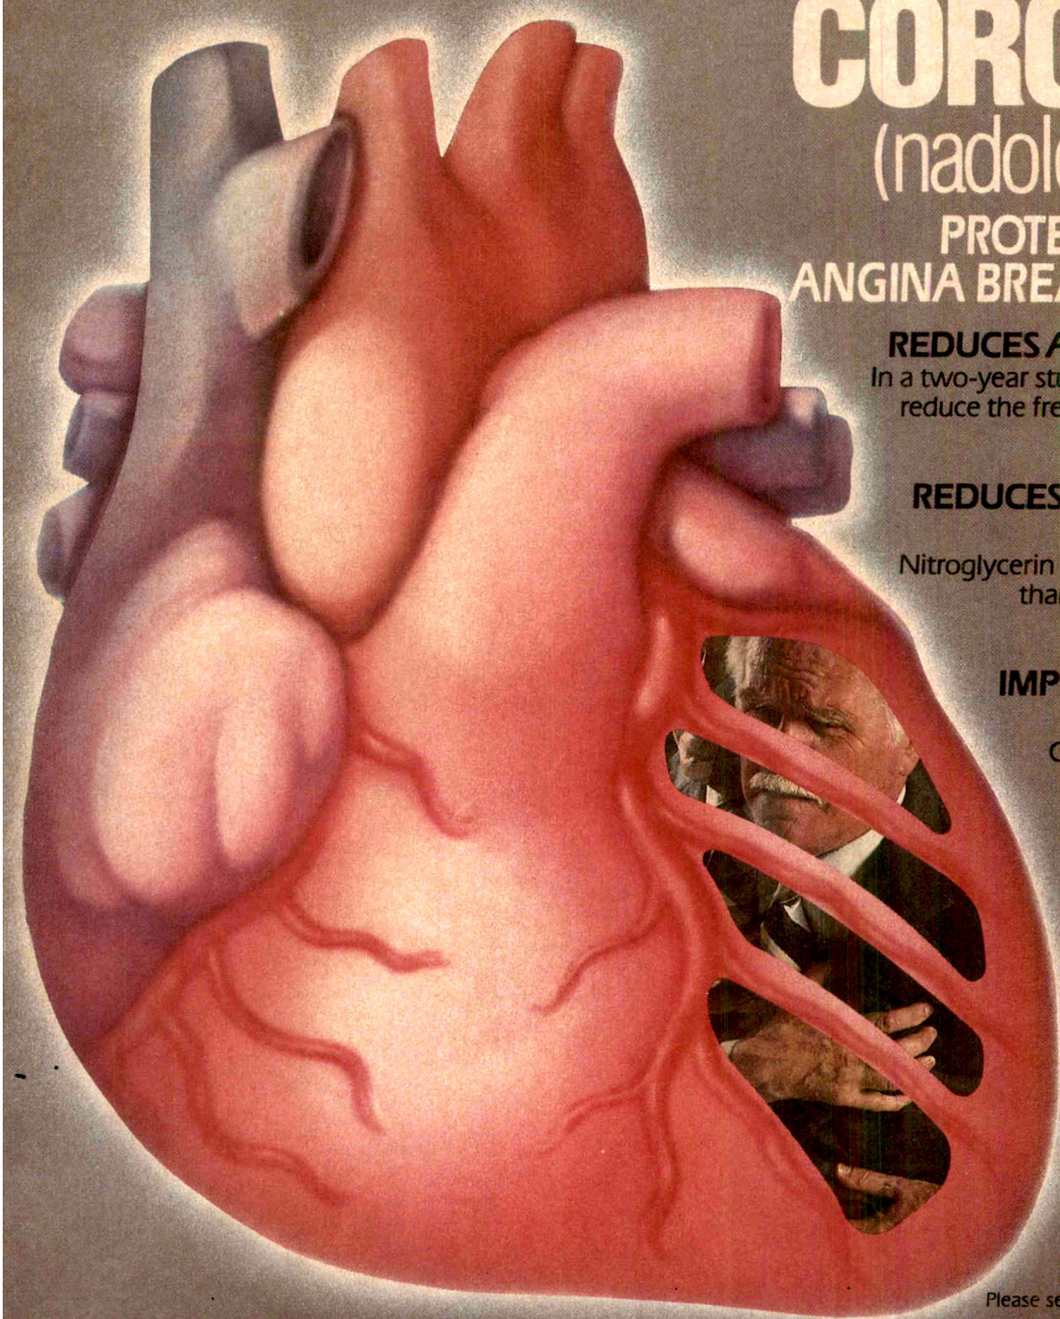
SQUIBB

WHEN YOUR PATIENT IS TRAPPED BY ANGINA AND THE FEAR OF THE NEXT ATTACK



CORGARD®
(nadolol tablets)

PROTECTS AGAINST ANGINA BREAKTHROUGH*

REDUCES ANGINA ATTACKS
In a two-year study, CORGARD helped reduce the frequency of attacks from 5.3 per week to 2.1.[1]

REDUCES NITROGLYCERIN NEED
Nitroglycerin requirements were less than half by the end of the two-year study.[1]

IMPROVES EXERCISE TOLERANCE
CORGARD significantly increases the patient's ability to participate in physical activity.[2]

*The syndrome of recurring symptoms compounded by the fear of impending attacks.

Please see brief summary of prescribing information on adjacent page.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

571 **Simultaneous Computer Mapping to Facilitate Intraoperative Localization of Accessory Pathways in Patients with Wolff-Parkinson-White Syndrome.** Jeffrey B. Kramer, Peter B. Corr, James L. Cox, Francis X. Witkowski, and Michael E. Cain

577 **Prospective Comparison of Holter Monitoring and Electrophysiologic Study in Patients with Coronary Artery Disease and Sustained Ventricular Tachyarrhythmias.** Charles D. Swerdlow and Jan Peterson

581 **Comparative Efficacy and Safety of Oral Tocainide and Quinidine for Benign and Potentially Lethal Ventricular Arrhythmias.** Joel Morganroth, Carl Oshrain, and Peter P. Steele

585 **Incidence of Proarrhythmic Effects from Quinidine in the Outpatient Treatment of Benign or Potentially Lethal Ventricular Arrhythmias.** Joel Morganroth and Leonard N. Horowitz

588 **Ambulatory Electrocardiographic Recordings at the Time of Fatal Cardiac Arrest.** Peter G. Milner, Edward V. Platia, Philip R. Reid, and Lawrence S.C. Griffith

593 **Usefulness of Programmed Stimulation in Predicting Efficacy of Propafenone in Long-Term Antiarrhythmic Therapy for Paroxysmal Supraventricular Tachycardia.** Matthias Manz, Gerhard Steinbeck, and Berndt Lüderitz

VALVULAR HEART DISEASE

CITRUS FRUIT-PUNCH

When your patients need Potassium Chloride.

K·LYTE/CL®

- effervescent tablets with delicious citrus or fruit-punch flavor
- each tablet in solution provides 25 mEq potassium chloride

K·LYTE/CL® 50

- provides 50 mEq potassium chloride for once-a-day convenience

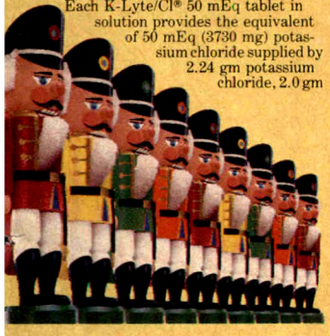
Unmatched safety of liquids, in convenient effervescent tablet form, convenient strengths *and* pleasant-tasting flavors

K-Lyte/Cl Effervescent Tablets Brief Summary

Caution: Federal Law Prohibits Dispensing Without Prescription

DESCRIPTION: Each K-Lyte/Cl® tablet in solution provides the equivalent of 25 mEq (1865 mg) potassium chloride supplied by 1.5 gm potassium chloride, 0.5 gm potassium bicarbonate and 0.91 gm L-lysine monohydrochloride and 0.55 gm citric acid.

Each K-Lyte/Cl® 50 mEq tablet in solution provides the equivalent of 50 mEq (3730 mg) potassium chloride supplied by 2.24 gm potassium chloride, 2.0 gm potassium bicarbonate and 3.65 gm L-lysine monohydrochloride and 1.0 gm citric acid.



INDICATIONS AND USAGE: Therapy or prophylaxis of potassium deficiency.

CONTRAINDICATIONS: Contraindicated in patients with hyperkalemia. Hyperkalemia may complicate chronic renal impairment, metabolic acidosis, acute dehydration, and extensive tissue breakdown. Concomitant administration of potassium salts and potassium-sparing diuretic can produce severe hyperkalemia.

WARNINGS: In patients with impaired potassium excreting mechanisms, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and may be asymptomatic. Use in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

PRECAUTIONS: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. Acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of reduced total body potassium. Therefore, the treatment of potassium depletion requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the ECG, and the clinical status of the patient.

Information for Patients: Patients should be carefully directed to completely dissolve each tablet.

Drug Interactions: Simultaneous administration of potassium supplements and a potassium-sparing diuretic as well as concomitant use of potassium supplements and salt substitutes can result in hyperkalemia (see Contraindications).

Usage in Pregnancy - Pregnancy Category C: It is not known whether K-Lyte products can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity.

Nursing Mothers: There is a potential for serious adverse reactions in nursing infants from oral potassium supplements given to the mother. Nursing or the drug should be discontinued based on the importance of the drug for the mother.

Usage in Children: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most common adverse reactions to oral potassium supplements are nausea, vomiting, diarrhea and abdominal discomfort. These side effects occu more frequently when the medication is not taken with food or is not diluted properly or dissolved completely.

Hyperkalemia occurs only rarely in patients with normal renal function receiving potassium supplements orally.

The Original

...the only clinically-tested dipyridamole

Reliquary, for the heart of Anne of Brittany
Museum of Nantes

Crafted entirely in gold, the reliquary bears an eloquent inscription extolling the virtue of Anne, Duchess of Brittany and Queen of France. The reliquary dates from 1513.

dipyridamole

Tablets of 25, 50 and 75 mg

Persantine®

The experienced dipyridamole

BRIEF SUMMARY

INDICATIONS—Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indication as follows:
"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency of, or eliminate, anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack. Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.
PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.
ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.
DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy. Tablets of 25, 50 and 75 mg. For complete details, please see the full prescribing information.

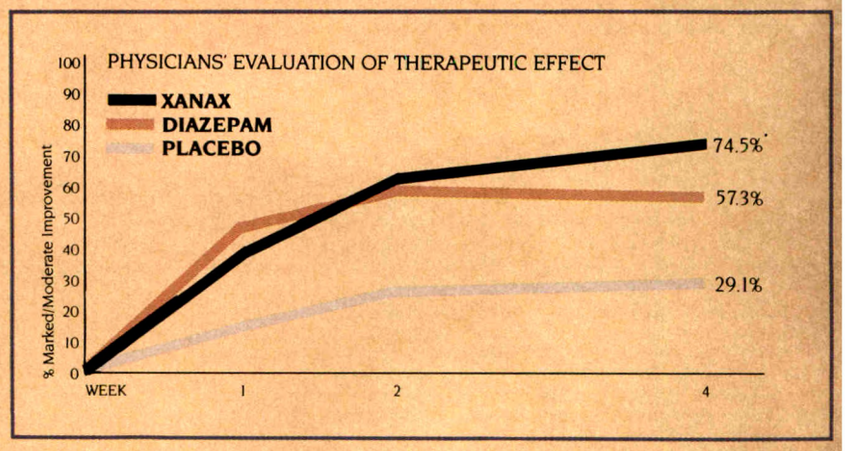
FOR CLINICAL ANXIETY

EFFICACY EQUAL TO DIAZEPAM WITH LESS DROWSINESS

In double-blind, placebo-controlled clinical trials in 976 patients with moderate to severe clinical anxiety, therapy with XANAX was compared to diazepam:*

Patients treated with XANAX *had a significantly lower incidence of drowsiness when compared directly to diazepam* therapy in *a 976-patient*, placebo-controlled, multicenter study:*

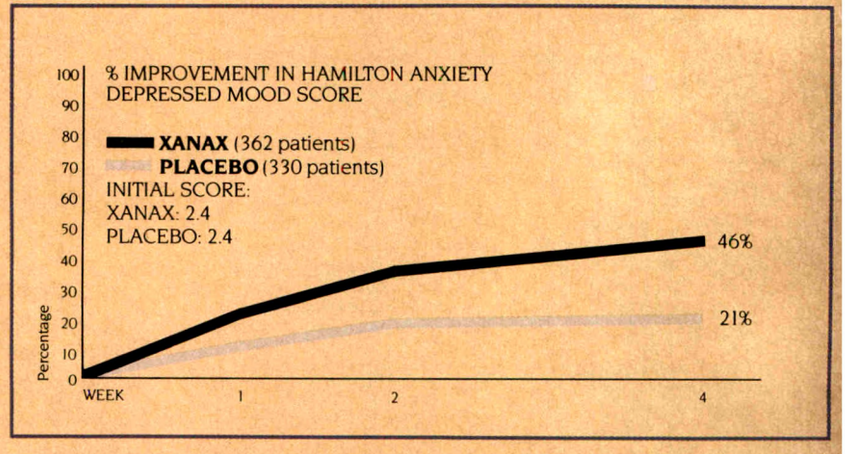


AND CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

EFFECTIVE IN CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

Patients with clinical anxiety may complain of having feelings of depression, such as sadness, blueness, or loneliness.

Depressed mood is one of 14 items on the Hamilton Anxiety Rating Scale. Special analysis of 692 anxious patients with a significant depressed mood item score showed that treatment with XANAX was significantly better than placebo in decreasing depressed mood score.



SIMPLE DOSAGE: XANAX 0.25–0.5 mg T.I.D.

The usual starting dose of XANAX is 0.25 to 0.5 mg, three times daily.

Please see next page for brief summary of prescribing information.

Xanax® 0.5 mg Tablets

alprazolam Ⓒ IV

alprazolam) Ⓒ

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: The dosage of XANAX Tablets should be reduced or withdrawn gradually, since withdrawal seizures have been reported upon abrupt withdrawal. If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation. (See Drug Interaction section.) Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage. (See Dosage and Administration.) Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about: (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central nervous system: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting, and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other side effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analysis are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. Withdrawal seizures have occurred upon rapid decrease or abrupt discontinuation of therapy. In all patients, dosage should be gradually tapered under close supervision. Patients with a history of seizures or epilepsy should not be abruptly withdrawn from XANAX. Addiction-prone individuals should be under careful surveillance. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

DOSAGE AND ADMINISTRATION
The usual starting dose is 0.25 to 0.5 mg, t.i.d. Maximum total daily dose is 4 mg. In the elderly or debilitated, the usual starting dose is 0.25 mg, two or three times daily. Reduce dosage gradually when terminating therapy, by no more than one milligram every three days.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION. B-3-S

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

571 **Simultaneous Computer Mapping to Facilitate Intraoperative Localization of Accessory Pathways in Patients with Wolff-Parkinson-White Syndrome**

JEFFREY B. KRAMER, PETER B. CORR, JAMES L. COX, FRANCIS X. WITKOWSKI, and MICHAEL E. CAIN

The clinical applicability of simultaneous intraoperative computer mapping from multiple sites was evaluated in 16 patients with the Wolff-Parkinson-White syndrome before surgical division of the accessory pathways. The computer mapping protocol permitted rapid, simultaneous recording and analysis of multiple epicardial and transmural electrograms along the atrioventricular groove. This approach facilitated intraoperative mapping by requiring only a single beat for analysis of anterograde and retrograde activation times, decreased cardiac manipulation during mapping, obviated the need for cardiopulmonary bypass, decreased the time required for mapping, permitted accurate study of nonsustained arrhythmias, and allowed rapid identification of multiple accessory pathways.

577 **Prospective Comparison of Holter Monitoring and Electrophysiologic Study in Patients with Coronary Artery Disease and Sustained Ventricular Tachyarrhythmias**

CHARLES D. SWERDLOW and JAN PETERSON

Baseline 24-hour Holter monitoring (HM) and electrophysiologic study (EPS) were compared in 32 consecutive patients with sustained ventricular tachyarrhythmias to determine the fraction of patients in which each could be performed and the fraction in which each could be used to guide therapy. Patients were excluded from HM if sustained ventricular tachycardia requiring termination occurred and from EPS if heart failure was sufficiently severe to cause excessive risk. More patients completed EPS than HM, but this difference was not significant (90% vs 71%, $p = 0.12$). Arrhythmias suitable for antiarrhythmic drug assessment were detected more frequently by EPS than HM: 87% vs 50% ($p = 0.003$) for all patients and 96% vs 70% ($p = 0.02$) for patients completing EPS or HM.

581 **Comparative Efficacy and Safety of Oral Tocainide and Quinidine for Benign and Potentially Lethal Ventricular Arrhythmias**

JOEL MORGANROTH, CARL OSHRAIN, and PETER P. STEELE

The antiarrhythmic efficacy and safety of tocainide and quinidine were compared in a double-blind, 3-center, parallel trial involving 133 patients with benign and potentially lethal ventricular arrhythmias (ventricular premature complexes [VPCs]). Baseline characteristics were not different between the 2 groups. Two weeks of placebo were followed by 8 weeks of active drug and then 2 weeks of placebo. Frequent Holter monitoring was used to judge efficacy. Ten of 27 patients (37%) receiving tocainide and 12 of 24 patients (50%) receiving quinidine had a 75% reduction in VPC frequency ($p > 0.25$). Total abolition of ventricular tachycardia occurred in 6 of 16 patients (37%) receiving tocainide and 6 of 13 patients (43%) receiving quinidine ($p > 0.25$). Conditions requiring discontinuation of therapy occurred in 18 of 67 patients (27%) receiving tocainide and 16 of 66 patients (24%) receiving quinidine (difference not significant). Quinidine caused a prolongation in the QT interval and tocainide caused a slight reduction. Thus, tocainide, the new oral analog of lidocaine, appears to be comparable to quinidine in safety and is slightly less effective in suppressing VPCs.

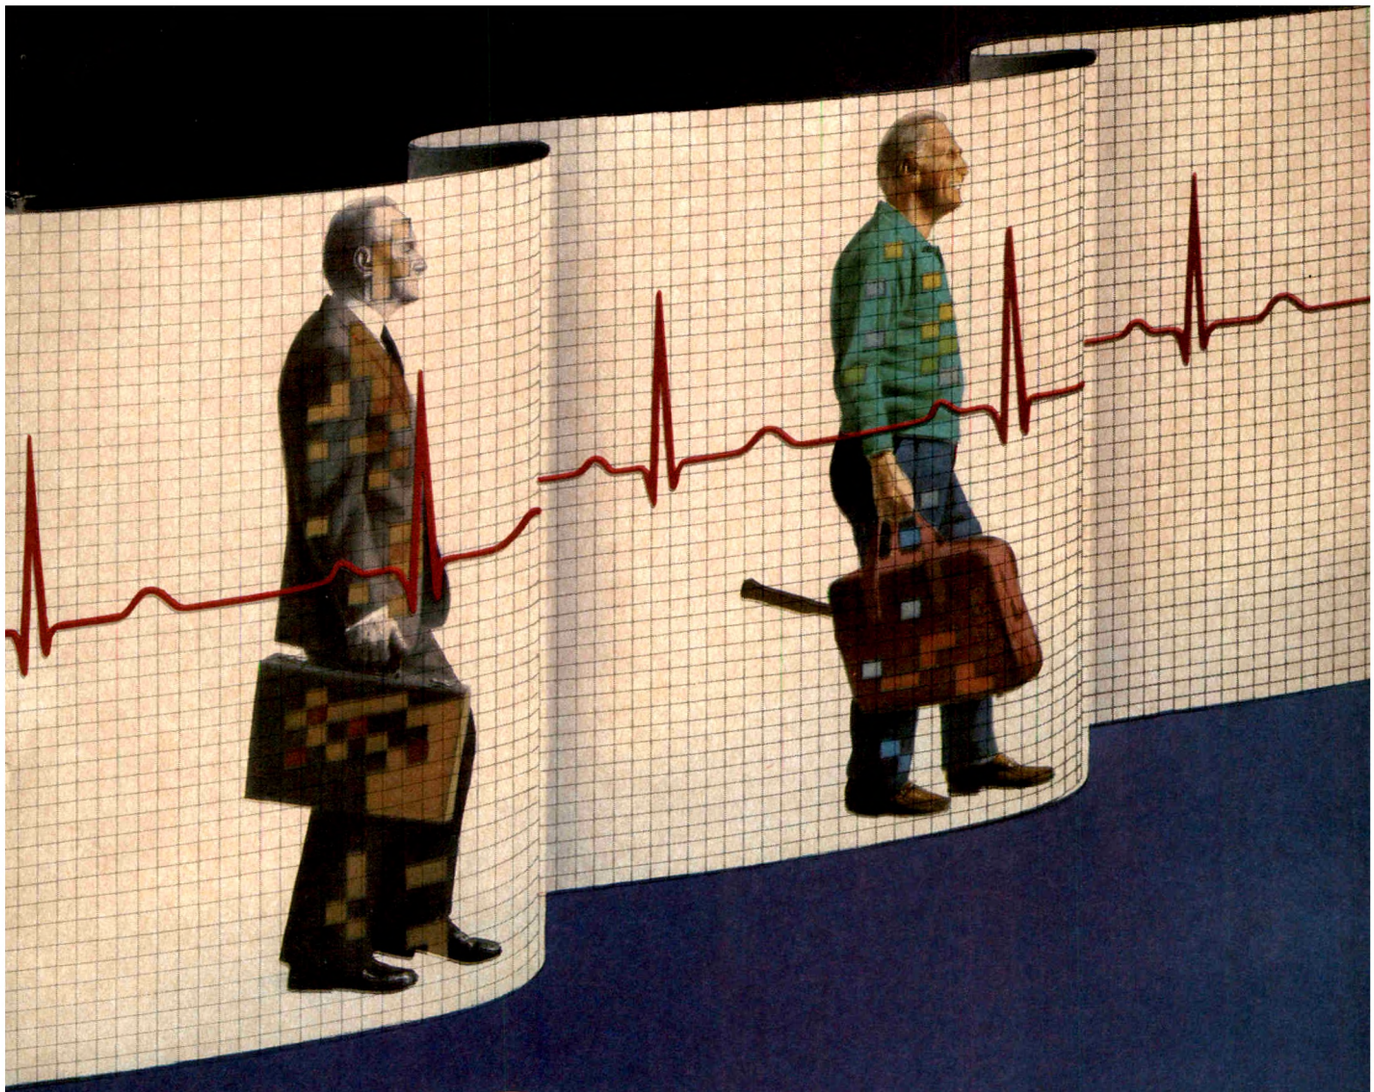
Safeguard the rhythm of life
BERLEX Laboratories, Inc., Wayne, New Jersey 07470



dura-tabs® SUSTAINED-RELEASE TABLETS 324 mg

Quinaglute®

quinidine gluconate

- Continuous arrhythmia control
- Well tolerated in long-term therapy[1]
- Less GI upset than with quinidine sulfate[2]
- B.I.D.* dosage for uninterrupted protection

Start the oral agent he can live with

*Some patients may require more frequent (t.i.d.) dosing
Please turn page for brief summary of prescribing information.

References: 1. Selzer A: *Heart Lung* 1982;11:20-23.
2. Podrid P: *Patient Care* 1981;15:100-132.

Dura-Tabs are indicated in the prevention and/or treatment of:
1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock)
2. Junctional (nodal) arrhythmias: A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).
CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.
WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine. 2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered. 3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring. 4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals. 5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity. 7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal. 8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.
PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk. *Information for Patients:* As with all solid oral medications, Quinaglute (quinidine gluconate) Dura-Tabs (sustained-release tablets) should be taken with an adequate amount of fluid, preferably in an upright position, to facilitate swallowing.

Drug Interactions: *Drug*	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.
Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.
Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.
Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.
ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea. Less frequently encountered adverse reactions:
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope; disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.

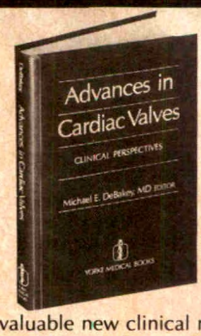
on Heart Valve Replacement Available Today!



Advances in Cardiac Valves
Clinical Perspectives

edited by
Michael E. DeBakey, MD
0-914316-40-0, 1983, 274pp., $35.00

This valuable new clinical reference provides a detailed update on many aspects of mechanical heart valve prostheses, including hemodynamics, clinical results, results in children, non-invasive assessments, special indications, and implant techniques. Each topic is presented in an easily understood style and format which facilitate the comprehension of recent developments in heart valve replacement for the busy clinician.

Each chapter is written by internationally respected physicians and medical scientists each of whom is pre-eminent in his field. All of the information has been co-ordinated by Dr. DeBakey to produce a very readable and informative volume on the state-of-the-art of heart valve replacement with mechanical prostheses. No cardiologist, cardiovascular surgeon, internist, or bioengineer can afford *not* to be knowledgeable about the information in this book.

585 **Incidence of Proarrhythmic Effects from Quinidine in the Outpatient Treatment of Benign or Potentially Lethal Ventricular Arrhythmias**

JOEL MORGANROTH and LEONARD N. HOROWITZ

The prevalence of proarrhythmic events secondary to the initiation of quinidine in outpatients with benign or potentially lethal ventricular arrhythmias was retrospectively reviewed in 360 patients treated with quinidine as part of 3 outpatient drug trials. These patients had at least 30 ventricular premature complexes (VPCs) per hour during placebo treatment and had no evidence of unstable clinical states, hypokalemia, digitalis toxicity, atrial fibrillation or a prolonged QT interval. Quinidine was dosed from 200 to 400 mg 4 times a day for 2 to 4 weeks and a proarrhythmic effect was defined by Holter monitoring. There was no difference in the demographic characteristics, response to quinidine therapy or side effects during quinidine treatment among the 3 trials. The proarrhythmic response rate was 6 of 360 (2%) and all patients were asymptomatic. Thus, quinidine can be safely initiated to outpatients as described above.

588 **Ambulatory Electrocardiographic Recordings at the Time of Fatal Cardiac Arrest**

PETER G. MILNER, EDWARD V. PLATIA, PHILIP R. REID, and LAWRENCE S.C. GRIFFITH

Ambulatory electrocardiographic recordings in 13 patients at the time of in-hospital cardiac arrest showed ventricular tachycardia (VT) to be the initial arrest arrhythmia in 12 patients. VT degenerated to ventricular fibrillation in 10 patients at a mean interval of 96 ± 31 seconds after cardiovascular collapse. A significant increase in VT runs occurred during the hour before arrest. Despite prompt resuscitation efforts, only 6 of 12 patients survived. Degeneration of VT to ventricular fibrillation within 30 seconds and a slower rate of VT at onset of arrest were associated with failure of resuscitation.

593 **Usefulness of Programmed Stimulation in Predicting Efficacy of Propafenone in Long-Term Antiarrhythmic Therapy for Paroxysmal Supraventricular Tachycardia**

MATTHIAS MANZ, GERHARD STEINBECK, and BERNDT LÜDERITZ

The electrophysiologic effects of intravenous and oral propafenone were evaluated in 24 patients with paroxysmal supraventricular tachycardia. Propafenone prolonged the effective refractory periods of the right atrium and the atrioventricular node. With propafenone, the cycle length of the reentrant tachycardia and the shortest atrial interval with 1:1 atrioventricular conduction increased markedly. The electrophysiologic effects of intravenous and oral propafenone were similar. Patients with complete suppression of supraventricular tachycardia appeared to have less recurrences during long-term therapy. Thus, acute electrophysiologic drug testing with propafenone can predict its efficacy during chronic therapy in most patients.

VALVULAR HEART DISEASE

598 **Effects of Atenolol on Exercise Capacity in Patients with Mitral Stenosis with Sinus Rhythm**

HERMAN O. KLEIN, PINHAS SARELI, COLON L. SCHAMROTH, YOONOOS CARIM, MENASHE EPSTEIN, and BRIDGET MARCUS

Exercise capacity is almost always impaired in patients with significant mitral stenosis and sinus rhythm, because elevation of left atrial pressure occurs with exercise-induced sinus tachycardia. Beta blockade with atenolol reduced mean heart rates at rest and during exercise in 13 patients with mitral stenosis in sinus rhythm ($p = 0.0015$) and significantly increased total exercise time ($p = 0.0015$) and maximal exercise capacity ($p = 0.0015$). Atenolol produces objective improvement of exercise capacity in patients with mitral stenosis in sinus rhythm. This is attributed to diminished effort-induced sinus tachycardia, thus improving left atrial emptying.

602 **Electrophysiologic Mechanisms of Provoked Atrial Flutter in Mitral Valve Prolapse Syndrome**

DAVID J. DOBMEYER, RONALD A. STINE, CARL V. LEIER, and STEPHEN F. SCHAAL

Patients with mitral valve prolapse (MVP) and sustained atrial flutter (AF) provoked by the extrastimulus technique in the catheterization laboratory were found to differ from patients without MVP with provokable AF by the absence of atrial conduction disease. The patients with MVP who had provokable AF had significant differences

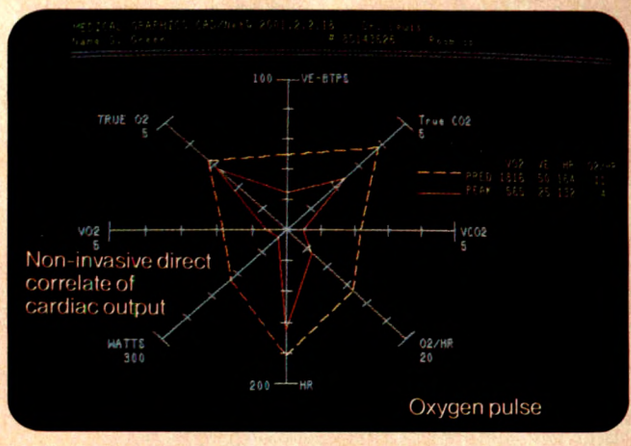
Medical Graphics System 2001 cardiodynamic imaging provides more, for comprehensive stress testing.

Stress testing is revolutionized with the CAD/Net™ Exercise Stress Testing System 2001 for non-invasive assessment of cardiac function. Real-time cardiodynamic imaging provides more clinically useful information about functional capacity and cardiac function than conventional stress testing methods.

Use the System 2001 simultaneously with your existing EKG and treadmill or cycle ergometer for:

- Early detection of coronary atherosclerosis, valvular and/or congestive heart disease (functional class impairment)
- Cardiac rehabilitation of CAB or PTCA patients (assessment of functional class improvement and patient prognosis)
- Evaluation of exercise effects of various pharmacologic agents for treatment of hypertension, congestive heart failure, coronary artery disease, arrhythmias, etc.
- Differentiation of cardiac versus pulmonary induced dyspnea and angina during exercise



Cardiodynamic Image ™

Patient Case: 56 year old with CHF. Note severe functional impairment upon limited exertion (class C), as indicated by a significantly depressed **V̇02** and **02 pulse** with compensatory HR increase.

Convenient, clinically applicable.

The automated System 2001 conducts the stress test protocol allowing physician/patient interaction. Real-time test results are immediately available on the cardiodynamic image screen in an easy to interpret graphic format. And, they can be stored for comparison with subsequent patient follow-up tests. The System 2001 saves both time and money.

The System 2001—a revolution in exercise testing.

For more information on how to maximize clinically useful data and make every stress test count, call us toll-free at **1-800-328-4138** or, return the coupon below.

between high and low right atrial effective refractory periods than did MVP patients without provokable AF and normal subjects. These findings suggest that inhomogeneities of refractory periods may cause AF in patients with MVP. This inhomogeneity may be a result of autonomic imbalance or abnormalities.

605 **Prognostic Significance of Exercise-Induced Left Ventricular Dysfunction in Chronic Aortic Regurgitation**
DAVID S. GEE, JACK E. JUNI, JOHN T. SANTINGA, and ANDREW J. BUDA

The significance of a preoperative decrease in exercise left ventricular (LV) ejection fraction (EF) in patients with chronic aortic regurgitation (AR) is uncertain. To examine this further, 23 patients were investigated who had hemodynamically significant AR and who underwent rest and exercise radionuclide angiography before and after valve replacement. Preoperatively, exercise LVEF decreased significantly ($p < 0.001$). Postoperatively, exercise LVEF increased significantly ($p < 0.01$ compared to preoperative values). After a mean follow-up of 30 months, most patients who survived surgery were asymptomatic and there were no late cardiac related deaths. Our data suggest that most patients improve exercise LVEF after valve replacement for chronic AR despite an abnormal preoperative exercise study. In addition, a preoperative decrease in exercise LVEF in patients with significant AR does not predict a poor postoperative outcome.

610 **Clinical and Echocardiographic Observations in Pulmonary Valve Endocarditis**
ANNE-CLAUDE CREMIEUX, SERGE WITCHITZ, MARIE-CHRISTINE MALERGUE, MICHEL WOLFF, DANIEL VITTECOCQ, JEAN-LOUIS VILDE, JACQUES FROTTIER, PIERRE ETIENNE VALERE, CLAUDE GIBERT, and ADRIEN G. SAIMOT

Clinical and echocardiographic data on 12 patients with pulmonary valve endocarditis are described. Seven patients had isolated pulmonary endocarditis and in 5 patients other valves were infected (aortic, tricuspid or mitral or all 3). Two patients were heroin addicts and 4 had underlying heart disease (congenital heart disease [3 patients] or aortic regurgitation [1 patient]). The organisms involved were alpha streptococci in 3 patients (all with underlying heart disease), *Staphylococcus aureus* in 4, *Streptococcus D bovis* in 1 patient and *Candida guillermondii* in 1. M-mode and 2-dimensional echocardiography, performed in 10 patients, revealed vegetations in 8. Pulsed Doppler echocardiography, performed in 6 patients, revealed pulmonary regurgitation in all 6. Four patients underwent surgery, 4 died, including 1 patient after heart surgery, and 5 recovered with antibiotic treatment.

CARDIOMYOPATHY

614 **Echocardiographic and Doppler Flow Observations in Obstructed and Nonobstructed Hypertrophic Cardiomyopathy**
JULIUS M. GARDIN, ALI DABESTANI, GORDON A. GLASGOW, SAMUEL BUTMAN, CORA S. BURN, and WALTER L. HENRY

Doppler ascending aortic flow velocity was recorded in 20 patients with hypertrophic cardiomyopathy: 12 with left ventricular (LV) outflow gradients at rest (obstructed HC) and 8 without significant gradients (nonobstructed HC) and in 20 normal subjects. Peak aortic flow velocity was similar in all 3 groups. However, mean ejection time from the Doppler tracing or aortic valve echogram was significantly longer in patients with obstructed HC (345 ± 30 ms) than in those with nonobstructed HC (296 ± 24 ms, $p < 0.02$) or normal subjects (294 ± 19 ms, $p < 0.01$). A rapid midsystolic decrease in aortic flow velocity was seen in 11 of 12 patients with obstructed HC, but not in those with nonobstructed HC or normal subjects. Furthermore, Doppler left atrial recordings showed mitral regurgitation in 4 of 5 patients with obstructed HC but in none of 6 patients with nonobstructed HC. Continued LV minor-axis shortening and mitral regurgitant flow after mitral valve–septal contact suggests that early deceleration of aortic flow in the patient with obstructed HC is at least partially a result of impedance to LV outflow by the mitral valve with redirection of blood into the left atrium.

MISCELLANEOUS TOPICS

623 **Primary Acute Pericardial Disease: A Prospective Series of 231 Consecutive Patients**
G. PERMANYER-MIRALDA, J. SAGRISTÁ-SAULEDA, and J. SOLER-SOLER

A series of 231 patients with primary acute pericardial disease were studied according to a prospective protocol. In 32 patients (14%) a specific etiologic diagnosis was made. Diagnostic pericardiocentesis (32 patients) was performed when clinical activity and effusion persisted for longer than 1 week or when purulent pericarditis was

For hypertensive emergency

TRANDATE® INJECTION 20 ml, 5 mg/ml

labetalol HCl/Glaxo

The "beta-dilator™" response: control within minutes

Action within a minute. Trandate® (labetalol HCl/Glaxo) Injection rapidly, predictably lowers blood pressure by lowering total peripheral resistance (TPR), while maintaining cardiac output.[1,2] The "beta-dilator™" effect of simultaneous beta blockade and alpha blockade-induced vasodilation is apparent within a minute.

Rapid control. Full effect of an IV dose is apparent in 5 to 10 minutes: helps avoid hypotensive "overshoot," facilitates monitoring.

Cost control. Rapid effect may shorten hospital stay and beneficially affect costs under DRG's.

Well tolerated.* The most commonly reported adverse reactions: postural hypotension,† dizziness,† paresthesias, increased sweating and nausea.

Smooth transition to oral therapy with the same agent. Control of hypertensive crisis with Trandate Injection allows continued control on oral therapy with no need to change agents.

Trandate Injection—the "beta-dilator™" response to hypertensive emergencies...another original product of Glaxo research.

* Patients should always be kept in a supine position during IV drug administration. See **DOSAGE AND ADMINISTRATION** section of Prescribing Information before initiating therapy.

† The episodes of postural hypotension and dizziness occurred primarily in one study in which patients were placed in an upright position within three hours of dosing for evaluation.

For a discussion of **ADVERSE REACTIONS**, please see Brief Summary of Prescribing Information on the last page of this advertisement.

Glaxo

For hypertensive emergency

TRANDATE® INJECTION 20 ml, 5 mg/ml

labetalol HCl/Glaxo

The "beta-dilator"™ response: control within minutes

- Trandate Injection can be administered as repeated IV injections, or by continuous infusion
- After initial dosing, further blood pressure reductions can be achieved with additional injections or by slow continuous infusion
- Discontinue Trandate Injection when blood pressure goal is achieved—when supine blood pressure has begun to rise, oral therapy may be initiated
- Patients should be kept in the supine position during IV drug administration. See **DOSAGE AND ADMINISTRATION** section of Prescribing Information before initiating therapy

For a discussion of **ADVERSE REACTIONS**, please see Brief Summary of Prescribing Information on the last page of this advertisement.

TRANDATE® Injection
(labetalol hydrochloride)

BRIEF SUMMARY OF PRESCRIBING INFORMATION

INDICATIONS AND USAGE: TRANDATE® (labetalol HCl) Injection is indicated for control of blood pressure in severe hypertension.

CONTRAINDICATIONS: TRANDATE® Injection is contraindicated in bronchial asthma, overt cardiac failure, greater than first degree heart block, cardiogenic shock, and severe bradycardia (see **WARNINGS**).

WARNINGS: Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure. Beta blockade carries a potential hazard of further depressing myocardial contractility and precipitating more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, labetalol HCl can be used with caution in patients with a history of heart failure who are well-compensated. Congestive heart failure has been observed in patients receiving labetalol HCl. Labetalol HCl does not abolish the inotropic action of digitalis on heart muscle.

In Patients Without a History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitilization and diuretic, TRANDATE® therapy should be withdrawn (gradually, if possible).

Ischemic Heart Disease: Angina pectoris has not been reported upon labetalol HCl discontinuation. However, following abrupt cessation of therapy with some beta-blocking agents in patients with coronary artery disease, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Therefore, such patients should be cautioned against interruption of therapy without the physician's advice. Even in the absence of overt angina pectoris, when discontinuation of TRANDATE is planned, the patient should be carefully observed and should be advised to limit physical activity. If angina markedly worsens or acute coronary insufficiency develops, TRANDATE administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken.

Nonallergic Bronchospasm (eg, chronic bronchitis and emphysema): Since TRANDATE Injection at the usual intravenous therapeutic doses has not been studied in patients with nonallergic bronchospastic disease, it should not be used in such patients.

Pheochromocytoma: Intravenous labetalol HCl has been shown to be effective in lowering the blood pressure and relieving symptoms in patients with pheochromocytoma; higher than usual doses may be required. However, paradoxical hypertensive responses have been reported in a few patients with this tumor; therefore, use caution when administering labetalol HCl to patients with pheochromocytoma.

Diabetes Mellitus and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (eg, tachycardia) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; it may therefore be necessary to adjust the dose of antidiabetic drugs.

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial. Protracted severe hypotension and difficulty in restarting or maintaining a heartbeat have been reported with beta-blockers. The effect of labetalol HCl's alpha-adrenergic activity has not been evaluated in this setting.

A synergism between labetalol HCl and halothane anesthesia has been shown (see **Drug Interactions**).

Rapid Decreases of Blood Pressure: Caution must be observed when reducing severely elevated blood pressure. Although such findings have not been reported with intravenous labetalol HCl, a number of adverse reactions, including cerebral infarction, optic nerve infarction, angina and ischemic changes in the electrocardiogram, have been reported with other agents when severely elevated blood pressure was reduced over time courses of several hours to as long as 1 or 2 days. The desired blood pressure lowering should therefore be achieved over as long a period of time as is compatible with the patient's status.

PRECAUTIONS: General: ***Impaired hepatic function*** may diminish metabolism of TRANDATE® Injection.

Hypotension: Symptomatic postural hypotension (incidence 58%) is likely to occur if patients are tilted or allowed to assume the upright position within 3 hours of receiving TRANDATE Injection. Therefore, the patient's ability to tolerate an upright position should be established before permitting any ambulation.

Jaundice or Hepatic Dysfunction: On rare occasions, oral labetalol HCl has been associated with jaundice (both hepatic and cholestatic). It is therefore recommended that treatment with labetalol HCl be stopped immediately should a patient develop jaundice or laboratory evidence of liver injury. Both have been shown to be reversible on stopping therapy.

Information for Patients: The following information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. During and immediately following (for up to 3 hours) TRANDATE Injection, the patient should remain supine. Subsequently, the patient should be advised on how to proceed gradually to become ambulatory, and should be observed at the time of first ambulation.

When the patient is started on TRANDATE Tablets, following adequate control of blood pressure with TRANDATE Injection, appropriate directions for titration of dosage should be provided (see **DOSAGE AND ADMINISTRATION**).

As with all drugs with beta-blocking activity, certain advice to patients being treated with labetalol HCl is warranted: While no incident of the abrupt withdrawal phenomenon (exacerbation of angina pectoris) has been reported with labetalol HCl, dosing with TRANDATE Tablets should not be interrupted or discontinued without a physician's advice. Patients being treated with TRANDATE Tablets should consult a physician at any sign of impending cardiac failure. Also transient scalp tingling may occur, usually when treatment with TRANDATE Tablets is initiated (see **ADVERSE REACTIONS**).

Laboratory Tests: Routine laboratory tests are ordinarily not required before or after intravenous labetalol HCl. In patients with concomitant illnesses, such as impaired renal function, appropriate tests should be done to monitor these conditions.

Drug Interactions: Since TRANDATE (labetalol HCl) Injection may be administered to patients already being treated with other medications, including other antihypertensive agents, careful monitoring of these patients is necessary to detect and treat promptly any undesired effect from concomitant administration.

In one survey, 2.3% of patients taking labetalol HCl orally in combination with tricyclic antidepressants experienced tremor as compared to 0.7% reported to occur with labetalol HCl alone. The contribution of each of the treatments to this adverse reaction is unknown, but the possibility of a drug interaction cannot be excluded.

Drugs possessing beta-blocking properties can blunt the bronchodilator effect of beta-receptor agonist drugs in patients with bronchospasm; therefore, doses greater than the normal anti-asthmatic dose of beta-agonist bronchodilator drugs may be required.

Cimetidine has been shown to increase the bioavailability of labetalol HCl administered orally. Since this could be explained either by enhanced absorption or by an alteration of hepatic metabolism of labetalol HCl, special care should be used in establishing the dose required for blood pressure control in such patients.

Synergism has been shown between halothane anesthesia and intravenously administered labetalol HCl. During controlled hypotensive anesthesia using labetalol HCl in association with halothane, high concentrations (3% or above) of halothane should not be used because the degree of hypotension will be increased and because of the possibility of a large reduction in cardiac output and an increase in central venous pressure. The anesthesiologist should be informed when a patient is receiving labetalol HCl.

Labetalol HCl blunts the reflex tachycardia produced by nitroglycerin without preventing its hypotensive effect. If labetalol HCl is used with nitroglycerin in patients with angina pectoris, additional antihypertensive effects may occur.

Drug/Laboratory Test Interactions: The presence of a metabolite of labetalol in the urine may result in falsely increased levels of urinary catecholamines when measured by a nonspecific trihydroxyindole (THI) reaction. In screening patients suspected of having a pheochromocytoma and being treated with labetalol HCl, specific radioenzymatic or high performance liquid chromatography assay techniques should be used to determine levels of catecholamines or their metabolites.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term oral dosing studies with labetalol HCl for 18 months in mice and for 2 years in rats showed no evidence of carcinogenesis. Studies with labetalol HCl, using dominant lethal assays in rats and mice, and exposing microorganisms according to modified Ames tests, showed no evidence of mutagenesis.

Pregnancy Category C: Teratogenic studies have been performed with labetalol in rats and rabbits at oral doses up to approximately 6 and 4 times the MRHD, respectively. No reproducible evidence of fetal malformations was observed. Increased fetal resorptions were seen in both species at doses approximating the MRHD. There are no adequate and well-controlled studies in pregnant women. Labetalol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects: Infants of mothers who were treated with labetalol HCl for hypertension during pregnancy did not appear to be adversely affected by the drug. Oral administration of labetalol to rats during late gestation through weaning at doses of 2 to 4 times the MRHD caused a decrease in neonatal survival.

Labor and Delivery: Labetalol HCl given to pregnant women with hypertension did not appear to affect the usual course of labor and delivery.

Nursing Mothers: Small amounts of labetalol (approximately 0.004% of the maternal dose) are excreted in human milk. Caution should be exercised when TRANDATE® (labetalol HCl) Injection is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: TRANDATE® Injection is usually well tolerated. Most adverse effects have been mild and transient and, in controlled trials involving 92 patients, did not require labetalol HCl withdrawal. Symptomatic postural hypotension (incidence 58%) is likely to occur if patients are tilted or allowed to assume the upright position within 3 hours of receiving TRANDATE Injection. Moderate hypotension occurred in 1 of 100 patients while supine. Increased sweating was noted in 4 of 100 patients, and flushing occurred in 1 of 100 patients.

The following also were reported with TRANDATE Injection with the incidence per 100 patients as noted:

Cardiovascular System: Ventricular arrhythmia in 1.

Central and Peripheral Nervous Systems: Dizziness in 9; tingling of the scalp/skin in 7; hypoesthesia (numbness) and vertigo in 1 each.

Gastrointestinal System: Nausea in 13; vomiting in 4; dyspepsia and taste distortion in 1 each.

Metabolic Disorders: Transient increases in blood urea nitrogen and serum creatinine levels occurred in 8 of 100 patients; these were associated with drops in blood pressure, generally in patients with prior renal insufficiency.

Psychiatric Disorders: Somnolence/yawning in 3.

Respiratory System: Wheezing in 1.

Skin: Pruritus in 1.

The incidence of adverse reactions depends upon the dose of labetalol HCl. The largest experience is with oral labetalol HCl (see TRANDATE Tablet Product Information for details.) Certain of the side effects increased with increasing oral dose as shown in the table below which depicts the entire U.S. therapeutic trials data base for adverse reactions that are probably or possibly dose-related.

Labetalol HCl Daily Dose (mg)	**200**	**300**	**400**	**600**	**800**	**900**	**1200**	**1600**	**2400**
Number of Patients	522	181	606	608	503	117	411	242	175
Dizziness (%)	2	3	3	3	5	1	9	13	16
Fatigue	2	1	4	4	5	3	7	6	10
Nausea	<1	0	1	2	4	0	7	11	19
Vomiting	0	0	<1	<1	<1	0	1	2	3
Dyspepsia	1	0	2	1	1	0	2	2	4
Paresthesias	2	0	2	2	1	1	2	5	5
Nasal Stuffiness	1	1	2	2	2	2	4	5	6
Ejaculation Failure	0	2	1	2	3	0	4	3	5
Impotence	1	1	1	1	2	4	3	4	3
Edema	1	0	1	1	1	0	1	2	2

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with labetalol HCl during investigational use and extensive foreign marketing experience.

Clinical Laboratory Tests: Among patients dosed with TRANDATE Tablets, there have been reversible increases of serum transaminases in 4% of patients tested and, more rarely, reversible increases in blood urea.

OVERDOSAGE: Overdosage with TRANDATE® Injection causes excessive hypotension which is posture sensitive and, sometimes, excessive bradycardia. Patients should be laid supine and their legs raised if necessary to improve the blood supply to the brain. The following additional measures should be employed if necessary: **Excessive bradycardia**—administer atropine (3.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously. **Cardiac failure**—administer a digitalis glycoside and a diuretic. **Hypotension**—administer vasopressors, eg, norepinephrine. There is pharmacological evidence that norepinephrine may be the drug of choice. **Bronchospasm**—administer a beta$_2$-stimulating agent and/or a theophylline preparation.

If overdosage with labetalol HCl follows oral ingestion, gastric lavage or pharmacologically induced emesis (using syrup of ipecac) is useful for removal of the drug shortly after ingestion. Labetalol HCl can be removed from the general circulation by hemodialysis.

The oral LD_{50} value of labetalol HCl in the mouse is approximately 600 mg/kg and in the rat is greater than 2 g/kg. The intravenous LD_{50} in these species is 50 to 60 mg/kg.

DOSAGE AND ADMINISTRATION: Initiation of Dosing with TRANDATE Tablets: Subsequent oral dosing with TRANDATE Tablets should begin when it has been established that the supine diastolic blood pressure has begun to rise. The recommended initial dose is 200 mg, followed in 6-12 hours by an additional dose of 200 mg or 400 mg, depending on the blood pressure response. Thereafter, **inpatient titration with TRANDATE Tablets may proceed as follows:**

Inpatient Titration Instructions

Regimen	Daily Dose*
200 mg bid	400 mg
400 mg bid	800 mg
800 mg bid	1600 mg
1200 mg bid	2400 mg

*If needed, the total daily dose may be given in three divided doses.

While in the hospital, the dosage of TRANDATE (labetalol HCl) Tablets may be increased at one-day intervals to achieve the desired blood pressure reduction.

For subsequent outpatient titration or maintenance dosing see TRANDATE Tablets Product Information **DOSAGE AND ADMINISTRATION** for additional recommendations.

HOW SUPPLIED: TRANDATE® Injection, 5 mg/ml, is supplied in 20 ml (100 mg) ampules, box of 1 (NDC 0173-0350-59).

Store between 2° and 30° C (36° and 86° F.) Do not freeze.

Glaxo

Glaxo, Inc., Research Triangle Park, NC 27709

suspected; therapeutic pericardiocentesis (44 patients) was performed to treat tamponade. Diagnostic biopsy (20 patients) was carried out when illness persisted for longer than 3 weeks; therapeutic biopsy was performed whenever pericardiocentesis failed to relieve tamponade. The diagnostic yield difference between diagnostic (6%) and therapeutic (35%) procedures was significant ($p < 0.001$). Thus, a diagnostic procedure is not warranted as a routine method. A choice between therapeutic pericardiocentesis and biopsy is circumstantial and has to be individualized. Only through a systematic approach can a substantial diagnostic yield be reached in primary acute pericardial disease.

631 Post-Cardiac Injury Syndrome and an Increased Humoral Immune Response Against the Major Contractile Proteins (Actin and Myosin)

IVAN DE SCHEERDER, JOEL VANDEKERCKHOVE, JOHAN ROBBRECHT, LUC ALGOED, MARC DE BUYZERE, JORIS DE LANGHE, GUIDO DE SCHRIJVER, and DENIS CLEMENT

Two models of cardiac injury were studied—cardiotomy (CT) and acute myocardial infarction (AMI)—and the level of anti-heart antibodies was determined. Significantly more patients had post–cardiac injury syndrome (PCIS) after CT than after AMI. CT patients showed a significantly higher humoral immune response than the AMI patients.

634 Cardiovascular Deconditioning Produced by 20 Hours of Bedrest with Head-Down Tilt (−5°) in Middle-Aged Healthy Men

F. ANDREW GAFFNEY, J.V. NIXON, ERLING S. KARLSSON, WILLIAM CAMPBELL, A.B.C. DOWDEY, and C. GUNNAR BLOMQVIST

Cardiovascular deconditioning after prolonged bedrest has been attributed mainly to inactivity. To examine the role of body fluid shifts, 5 healthy middle-aged men were studied before, during and after a 20-hour period of bedrest with head-down tilt (−5°). This intervention produces a marked central shift of intravascular and interstitial fluid, but the short duration minimizes effects of inactivity. Central venous pressure, cardiac output and stroke volume increased initially but returned to baseline levels within 20 hours. Supine central venous pressure after tilt was lower than the value before tilt. After tilt there was orthostatic intolerance and a decreased maximal oxygen consumption associated with higher heart rates, lower stroke volumes and a 0.51-liter decrease in blood volume. These hemodynamic conditions were qualitatively and quantitatively similar to those seen after 2 to 3 weeks of bedrest or spaceflight. The results support the concept that cardiovascular deconditioning after bedrest is primarily an adaptation to a postural fluid shift rather than to inactivity.

639 Safety of Outpatient Cardiac Catheterizations

W. PETER KLINKE, GEORGE KUBAC, TAL TALIBI, and SIMON J.K. LEE

All outpatient cardiac catheterizations performed over a 66-month period were analyzed. A total of 3,071 outpatient cardiac catheterizations (83% of all catheterizations) were performed. The Judkins approach was used in over 98% of the catheterizations and 79% of the patients had both right- and left-sided cardiac catheterizations and coronary angiography. More than 86% of patients had significant coronary, valvular, myocardial or congenital heart disease. Thirty-four patients (1.1%) had a major complication, including 4 deaths (0.13%). Seventy patients (2.3%) were admitted for observation and discharged the following day with no major complications. More than 96% of all patients were discharged the same day. These results are similar to those of previous studies of cardiac catheterization. It is concluded that outpatient cardiac catheterization is safe and efficient.

642 Relation of Hemoglobin A_1 and Blood Glucose to Cardiac Function in Diabetes Mellitus

RICHARD S. GOLDWEIT, JEFFREY S. BORER, LOIS G. JOVANOVIC, ANDREW J. DREXLER, CLARE A. HOCHREITER, RICHARD B. DEVEREUX, and CHARLES M. PETERSON

The relation of short- and long-term changes in glucose metabolism to cardiac function was studied in 10 young insulin-dependent diabetic patients without clinical evidence of heart disease. Radionuclide cineangiography and echocardiography were used before and after both acute variations in blood glucose levels, and induction of chronic "tight glucose control" involving normalization of hemoglobin A_1. In diabetic patients, left ventricular (LV) ejection fraction (EF) at normal blood glucose concentration was indistinguishable from values in 11 normal

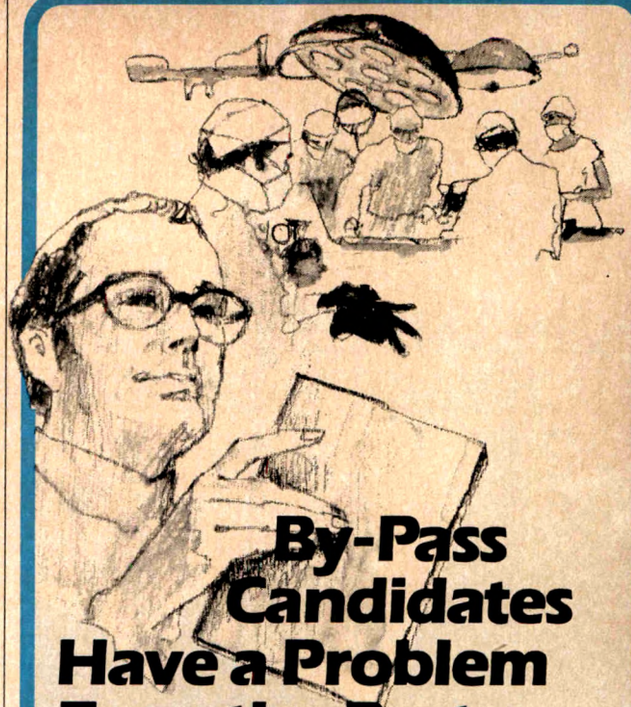
CLASSIFIED

ENDOWED CHAIR IN CARDIOVASCULAR RESEARCH:
The Department of Medicine of the University of Florida, College of Medicine is seeking applications for an endowed Chair in Cardiovascular Research. The endowed Chair, with assets in excess of one million dollars, was established by the State of Florida's Eminent Scholars Program and was made possible by generous contributions from the Suncoast Heart Association. The individual who will fill the Chair will have a full-time faculty appointment (Professor) in the Division of Cardiology of the Department of Medicine of the University of Florida College of Medicine. The appointee should have an M.D. or Ph.D. degree and a well-established, creative and productive investigative program in cardiovascular research. Salary is negotiable. Anticipated starting date is July 1, 1986. Interested individuals should write by February 28, 1986: James E. McGuigan, M.D., Chairman, Search Committee, Chair in Cardiovascular Research, Department of Medicine, College of Medicine, Box J-277, University of Florida Health Center, Gainesville, FL 32610. The University of Florida is an Equal Opportunity/Affirmative Action Employer.

Critical Care Specialist—BC in IM plus BC/BE in Cardio. or Resp. or Critical Care. Part-time ICU Director, Part-time practice in multisubspec. IM Group. Medical School Affiliated. Upstate NY. Please reply to Box 455, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

CARDIOLOGIST
Non-invasive/invasive Certified/Eligible Nuclear/Electrophysiology preferred (but not required) to join two man multifaceted practice in Sun Belt area. Practice is hospital base, consultative, office, CATH, including PTCA, pacemakers, non-invasive testing, including 2D Echo and Nuclear. Salary first year leading to partnership. Send CV to Box 445, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

Full-Time Faculty position at Assistant Professor level available January 1, 1986 in the Division of Cardiology, University of Colorado Health Sciences Center. Applicants must be fully trained in Cardiology with special emphasis on cardiac catheterization. Applicants should have extensive training and be desirous of growth in independent cardiovascular research; preference will be given to those with a dedicated interest in basic cardiovascular research. DEADLINE FOR APPLICATIONS is November 15, 1985. Send curriculum vitae to: L. D. Horwitz, M.D., Head, Division of Cardiology, University of Colorado Health Sciences Center, 4200 East Ninth Avenue, Box B-130, Denver, CO 80262. The University of Colorado Health Sciences Center is an equal Opportunity Employer.



By-Pass Candidates Have a Problem Even the Best Surgeon Can't Cure The problem is life insurance. Too often, patients who need by-pass surgery can't get life insurance at any price. But now, that's a complication you can help remedy with this breakthrough...

Introducing Coronary Life℠...the only $250,000.00 life insurance program exclusively for angiogram and by-pass candidates.

That's right! By-pass surgery has evolved to a point where life insurance is now available prior to surgery, even prior to the angiogram.

Acceptance is guaranteed—for up to $250,000.00 of coverage—to angiogram and by-pass candidates age 40 to 60 who can say "no" to 4 simple health questions.

ASK FOR FREE PATIENT INFORMATION
This innovative program can give by-pass candidates the confidence about their families' financial security that additional life insurance can provide.

Simply ask for a package of free information that tells your patients how to get this coverage quickly and directly...with no salesman involved.

Coronary Life is available for the first time in most states, so write today for free information to:

REHABILITATION IN ISCHEMIC HEART DISEASE

Edited by **William P. Blocker, Jr., M.D.,** F.A.C.P., Chief, Rehabilitation Medicine Service, V.A. Hospital, Houston, Assistant Professor of Physical Medicine, Baylor College of Medicine, Houston, and **David Cardus,** M.D., F.A.C.C., Professor of Physiology and Rehabilitation, Baylor College of Medicine, Houston, Texas.

Heavily illustrated, this volume presents 60 self-contained chapters dealing with *all* aspects of rehabilitation of the patient with ischemic heart disease. The 45 noted contributors discuss topics such as: designing a cardiac rehabilitation center; methods of rehabilitation for the stroke patient, amputee, spinal cord injury patient who has had a heart attack; equipment needs for a cardiac rehabilitation center; and legal responsibilities of the physicians and therapists.

All major aspects, from epidemiology and pathogenesis through prevention and education are covered, including ambulatory monitoring of electrocardiogram and blood pressure; evaluation of degree of disability; and pathogenesis of atherosclerosis. This book contains the *most complete* list of cardiac risk factors to be found in any text. This encyclopedic guide to the total care and rehabilitation of cardiac patients is written for *every* member of the cardiac rehabilitation team.

Calan® TABLETS
80 mg and 120 mg
(verapamil HCl)

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block.

Warnings: Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction <30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension, usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Elevations of liver enzymes have been reported. Four cases have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.

Precautions: Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use.

Adverse Reactions: Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR <50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%); elevations of liver enzymes have been reported (see *Warnings*). The following reactions, reported in less than 0.5% of patients, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions, spotty menstruation, ecchymosis, bruising, gynecomastia, and psychotic symptoms. Overall continuation rate was 94.5% in 1,166 patients.

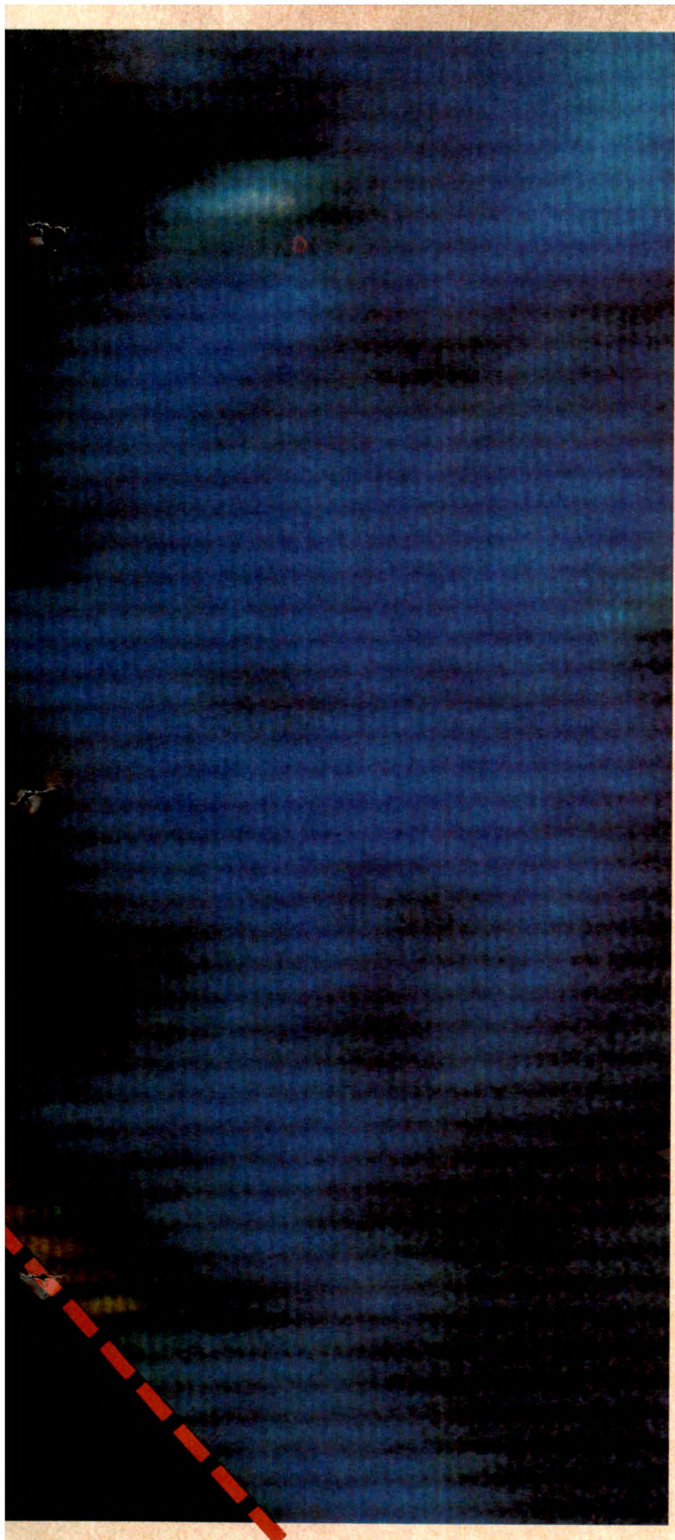
Toshiba Color Doppler, widening

Toshiba Medical Systems Europe, Schieweg 1, 2627 AN Delft/Holland. Tel. (015) 610121. ● Toshiba
● Toshiba Corporation, 1-1, Shibaura, 1-chome, Minato-Ku, Tokyo 105. Tel. 457-3273/3269, telex j 22587



Color comes to cardiac. And imaging has never looked better.

Until recently, fast accurate measurement, in real time, of blood flow and gradient was not possible by noninvasive means. Color Doppler analysis has changed this dramatically.

Toshiba's SSH-65A makes use of the Doppler Effect, whereby direction of flow produces changes in frequency, visible in gradations from red to blue. Flow abnormalities, for example regurgitations, are shown as color coded profiles and their severity can be quantified using the FFT-doppler spectrum.

A single unit offers total cardiac phase study, through two-dimensional real-time blood flow imaging; quantitative blood analysis in any ROI, through Pulsed Wave Doppler; and measurement of high blood flow by Continuous Wave Doppler.

The high resolution of the images naturally meets Toshiba's exacting requirements.

Never before has the invisible been rendered so visible!

the scope of diagnosis. TOSHIBA

merica Inc., Medical System Division, 2441 Michelle Drive, Tustin, CA 92680. Tel. (714) 730-5000.
Toshiba (Australia) PTY. LTD, Medical Division, 6-8 Byfield Street, North Ryde NSW 2113. Tel. (02) 888 3411

subjects. However, during hyperglycemia (about 300 mg/dl), average EF at rest was 61%, significantly higher than during normoglycemia (56%). No significant change in LV diastolic dimension was noted in association with shifts in glucose concentrations. Normalization of hemoglobin A_1 was achieved in 6 to 25 weeks, and had no significant effect on LVEF or response of systolic function to blood glucose levels. Thus, in insulin-dependent diabetic patients with overt heart disease, variation in blood glucose, but not hemoglobin A_1, is associated with small but significant changes in systolic function.

647 Electrophysiologic Evaluation of the Cardiac Conduction System and Its Autonomic Regulation in Familial Amyloid Polyneuropathy

BO LENNART BERGFELDT, BERT-OVE OLOFSSON, and KNUT OLOF EDHAG

Cardiac conduction disturbances are a salient feature in familial amyloid polyneuropathy (FAP), and amyloid infiltration of the conduction system has been found. This study is the first to have been undertaken to evaluate the function of the cardiac conduction system and its autonomic regulation during an invasive electrophysiologic study. Seven patients with FAP and with severe disturbances of the conduction system were studied and in 3 of them the parasympathetic regulation was found to be abolished. In 1 patient the observations indicated either vagal overactivity or denervation oversensitivity of the receptors. The function of β adrenoceptors was intact in all patients. Thus, dysfunction of the autonomic nervous regulation of the cardiac conduction system was found in 4 of 7 patients. Autonomic neuropathy of the heart in FAP has been demonstrated. However, most conduction abnormalities were irreversible, indicating amyloid infiltration of the conduction system as the predominant pathophysiologic mechanism.

653 Atrial Septal Aneurysm: Echopolycardiographic Study

CARLO LONGHINI, MARIA CHRISTIANA BRUNAZZI, GIANFRANCA MUSACCI, MARZIA CANEVA, ATTILIO BANDELLO, LORENZO BOLOMINI, MARIO BARBIERO, TIZIANO TOSELLI, and FRANCO BARBARESI

Atrial septal aneurysm with diagnosis during life is a rare reported anomaly. Among 4,000 routine echocardiograms, 23 cases of atrial septal aneurysm were found. Echocardiography revealed various motion patterns of atrial septal aneurysm. No phonomechanocardiographic findings were related to the presence of the atrial septal aneurysm. This study shows a greater incidence of aneurysm of the atrial septum in living patients than has been reported previously, and because of the potential risk, suggests the necessity for a systematic research of the atrial septal aneurysm during each routine echocardiographic examination, even if no specific clinical or phonocardiographic findings are present.

EXPERIMENTAL STUDIES

657 Measurement of Cardiac Output by Cine Computed Tomography

JEFFREY S. GARRETT, PETER LANZER, WERNER JASCHKE, ELIAS BOTVINICK, RICHARD SIEVERS, CHARLES B. HIGGINS, and MARTIN J. LIPTON

High-speed computed transmission tomography (cine CT) is a new noninvasive technique that is useful for the rapid, accurate quantitation of cardiac function. The capability of cine CT to assess cardiac output was examined in 10 mongrel dogs as an initial step in validating this method. Scans and thermodilution measurements of cardiac output were obtained at rest and during altered hemodynamic states induced by separate infusions of dobutamine and phenylephrine. Using the Stewart-Hamilton equation established for indicator dilution techniques, cardiac output was calculated. The results established a direct linear correlation ($r = 0.92$) between cine CT cardiac output and thermodilution cardiac output over a wide range of cardiac outputs (1.5 to 6.3 liters/min). This study demonstrates that cine CT can provide a reliable estimate of cardiac output noninvasively using contrast medium as an indicator in dogs.

662 Reduction of Laser-Induced Pathologic Tissue Injury Using Pulsed Energy Delivery

LAWRENCE I. DECKELBAUM, JEFFREY M. ISNER, ROBERTA FORTIN DONALDSON, RICHARD H. CLARKE, SYLVIE LALIBERTE, ALON S. AHARON, and JEFFREY S. BERNSTEIN

To determine if the pathologic injury typical of continuous-wave laser irradiation can be eliminated by altering the profile of laser energy delivery, 145 myocardial slices were irradiated using wavelengths of 248, 355, 488 to 515, 532, 1,064 or 10,600 nm from either an excimer, Nd-YAG, argon or CO_2 laser. Energy profile ranged from

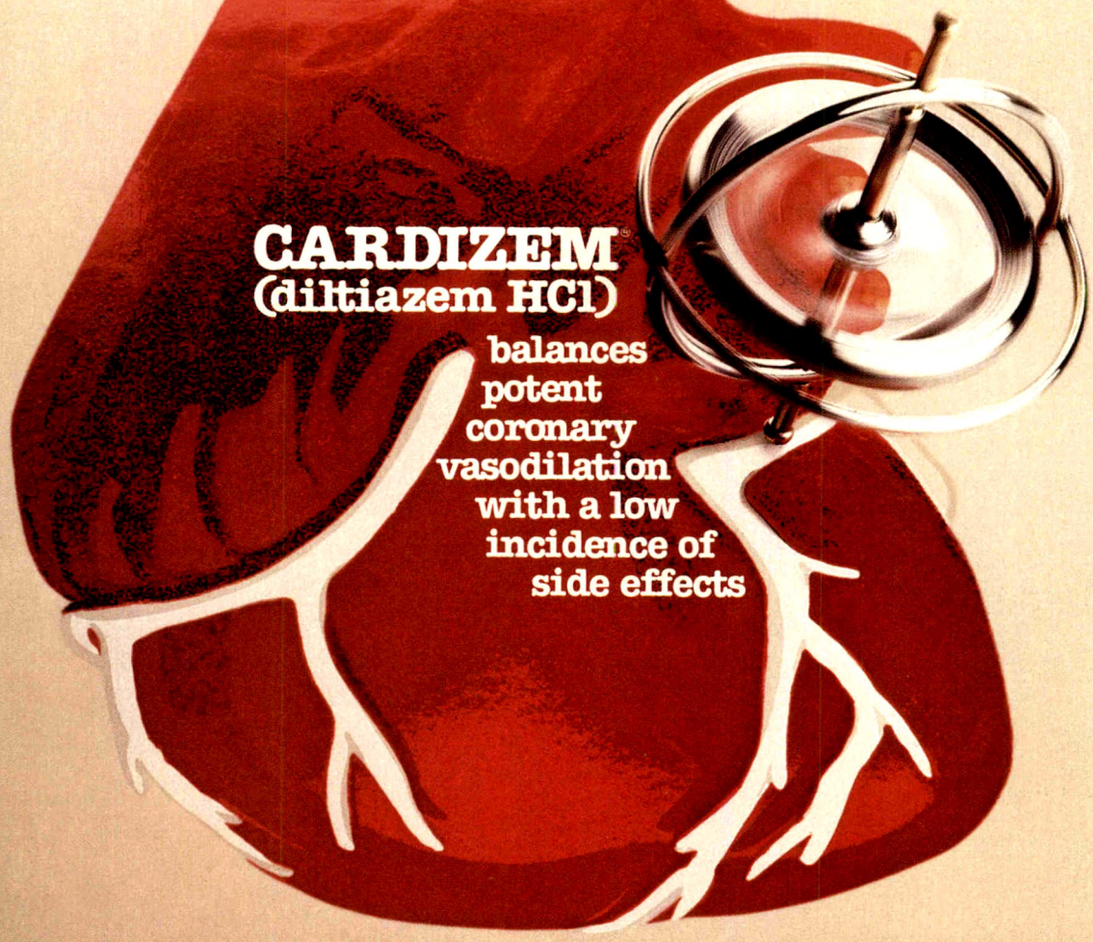
BALANCED CALCIUM CHANNEL BLOCKADE!



CARDIZEM®
(diltiazem HCl)

balances potent coronary vasodilation with a low incidence of side effects

Low incidence of side effects
CARDIZEM® (diltiazem HCl) produces an incidence of adverse reactions not greater than that reported with placebo therapy, thus contributing to the patient's sense of well-being.

*Cardizem is indicated in the treatment of angina pectoris due to coronary artery spasm and in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.

CARDIZEM®
(diltiazem HCl)

THE BALANCED CALCIUM CHANNEL BLOCKER

Please see full prescribing information on following page.

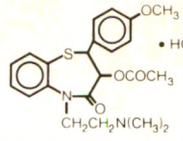
2/84

PROFESSIONAL USE INFORMATION

cardizem®
(diltiazem HCl)
30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM® (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy) -5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem hydrochloride for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanisms of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance, probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate-blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina. CARDIZEM has been effective in controlled trials in reducing angina frequency and increasing exercise tolerance.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (six of 1243 patients for 0.48%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** In rare instances, patients receiving CARDIZEM have exhibited reversible acute hepatic injury as evidenced by moderate to extreme elevations of liver enzymes. (See PRECAUTIONS and ADVERSE REACTIONS.)

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS).

Controlled and uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities. In healthy volunteers, diltiazem has been shown to increase serum digoxin levels up to 20%.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

The following represent occurrences observed in clinical studies which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are: edema (2.4%), headache (2.1%), nausea (1.9%), dizziness (1.5%), rash (1.3%), asthenia (1.2%), AV block (1.1%). In addition, the following events were reported infrequently (less than 1%) with the order of presentation corresponding to the relative frequency of occurrence.

Cardiovascular:	Flushing, arrhythmia, hypotension, bradycardia, palpitations, congestive heart failure, syncope.
Nervous System:	Paresthesia, nervousness, somnolence, tremor, insomnia, hallucinations, and amnesia.
Gastrointestinal:	Constipation, dyspepsia, diarrhea, vomiting, mild elevations of alkaline phosphatase, SGOT, SGPT, and LDH.
Dermatologic:	Pruritus, petechiae, urticaria, photosensitivity.
Other:	Polyuria, nocturia.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

The following postmarketing events have been reported infrequently in patients receiving CARDIZEM: erythema multiforme; leukopenia; and extreme elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK. However, a definitive cause and effect between these events and CARDIZEM therapy is yet to be established.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experience with oral diltiazem has been limited. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50}'s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. Although individual patients may respond to any dosage level, the average optimum dosage range appears to be 180 to 240 mg/day. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents:

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

Cardizem 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47) and in Unit Dose Identification Paks of 100 (NDC 0088-1771-49). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47) and in Unit Dose Identification Paks of 100 (NDC 0088-1772-49). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

Neurologist Marcel Malden is an avid hiker and a COSMOS® recipient.

A life like Marcel Malden's is worth every extra step we take.

Safety backup systems. It's a simple concept, but it represents one of the extra steps we take to bring you and your patients the most reliable pacemakers available today.

At Intermedics, we design critical function redundancy into every pacemaker we develop. Such as the primary timing control in the Quantum®–a crystal oscillator. It's backed up by a resistor-capacitor oscillator that takes over and continues pacing. Or the programmed bypass parameters that back up the magnetic reed switch in our COSMOS pulse generators. Or the multiple elective replacement indicators in both the Quantum and COSMOS. And the Rx2000 programmer that gives a clear indication if any of these safety systems activate.

Multiple backup systems like these assure that pacing continues even in the unlikely event of a critical component failure. It is this attention to detail that has earned Intermedics the highest reliability rating (and the lowest recall statistics) of any major pacemaker manufacturer.

When the fullness of life depends on the flawless performance of a sophisticated implant, there is no such thing as excessive quality control. Because there's more at stake than our reputation.

We believe these extra steps have helped make us the world's second largest pacemaker company in just eleven years. We know they are the reason Intermedics has consistently produced the most dependable line of pacemakers ever offered.

For documentation of our product reliability, just ask your Intermedics Representative. Or call us toll-free at 1-800-231-2330. (In Texas, 1-800-392-3726.) You'll see a record worth every extra step.

Intermedics Inc.®

Quality comes to life.™

©1985 Intermedics, Inc.

continuous to pulsed delivery at repetition rates of 1 Hz to 256 MHz, pulse duration of 0.2 to 358 ns, and pulse energies of 2 nJ to 370 mJ. Gross and light microscopic signs of thermal injury were eliminated by pulsed delivery at low repetition rates (less than 200 Hz) and high pulse energies (greater than 10 mJ).

667 **Effects of Hematoporphyrin Derivative and Photodynamic Therapy on Atherosclerotic Rabbits**

FRANK LITVACK, WARREN S. GRUNDFEST, JAMES S. FORRESTER, MICHAEL C. FISHBEIN, H.J.C. SWAN, ELIOT CORDAY, DAVID M. RIDER, I. STEWART McDERMID, THOMAS J. PACALA, and JAMES B. LAUDENSLAGER

This study was performed to confirm the selective uptake of hematoporphyrin derivative (HPD) within atheroma, to localize the site of uptake of HPD within the atheroma and to determine the potential for photodynamic therapy of atherosclerosis in the rabbit model. In 10 atherosclerotic rabbits that received HPD intravenously, all had HPD uptake within atheroma, but not within normal intima. Fluorescence microscopy revealed a diminishing concentration gradient of HPD from intimal surface layers inwards. Eight rabbits received from 5 to 20 mg/kg of HPD and photodynamic therapy with 636-nm red light. At 3 hours after irradiation there was no effect, but at 1 and 2 weeks some rabbits had less atheroma in treated segments than in controls. Histologic examination of treated segments revealed smooth muscle concentration near the intima, but similar findings occurred in some apparently nonirradiated areas.

672 **Effect of Intracoronary Verapamil on Infarct Size in the Ischemic, Reperfused Canine Heart: Critical Importance of the Timing of Treatment**

HUEY-MING LO, ROBERT A. KLONER, and EUGENE BRAUNWALD

To determine whether the beneficial effect of calcium blocking drugs occurs only during ischemia or during reperfusion as well, anesthetized dogs were subjected to 3 hours of occlusion of the left anterior descending coronary artery followed by 3 hours of reperfusion. In protocol A, intracoronary verapamil was begun 90 minutes after coronary occlusion and continued for 1 hour into reperfusion, while a control group received an infusion of saline solution. Area of necrosis, expressed as a percent of area at risk, was smaller in the verapamil group (29 ± 8%) than in the controls (57 ± 8%, $p < 0.05$). In protocol B, in which intracoronary verapamil was begun 5 minutes before blood reperfusion and continued throughout the 3 hours of reperfusion, there was no reduction of infarct size. Therefore, calcium blockade of ischemic myocytes delays death and enhances salvage produced by reperfusion. However, calcium blockade begun after prolonged coronary occlusion does not enhance reperfusion-induced myocardial salvage.

677 **Sudden Death and Experimental Acute Myocardial Infarction**

YVETTE TROLESE-MONGHEAL, PIERRE DUCHENE-MARULLAZ, JEAN-FRANCOIS TROLESE, MICHEL LEINOT, JEAN-CLAUDE LAMAR, and PIERRE LACROIX

Ligature of the anterior descending coronary artery in 658 dogs was fatal within 1 hour in 12% of the cases (instantaneous death) and within 24 hours in 25% of the cases (sudden death). Percentage of sudden death was proportional to the logarithm of the weight of the dogs in the range studied. Sudden death rate varied widely when small series of dogs were considered. Only with at least 50 to 60 dogs per series were reproducible figures obtained. Hence, reliable assessment of preventive action of drugs can only be made if experimental series of at least this size are used.

681 **Effect of Pulmonary Artery Distention on Systemic Vascular Resistance in Newborn Lambs**

JAY M. MILSTEIN and BOYD W. GOETZMAN

Acute distention of the left pulmonary artery in newborn lambs causes statistically significant increases in both systemic vascular resistance and aortic pressure. It is postulated that such changes may be important in affecting redistribution of cardiac output in the fetus, but they are probably too small to explain the elevated systemic vascular resistance observed in some infants with persistent fetal circulation.

CONGESTIVE HEART FAILURE

685 **Pharmacokinetics and Pharmacodynamics of Milrinone in Chronic Congestive Heart Failure**

JOSEPH R. BENOTTI, LAWRENCE J. LESKO, JANE E. McCUE, and JOSEPH S. ALPERT

The pharmacokinetics and hemodynamic effects of milrinone administered in an ascending intravenous bolus schedule were studied in patients with advanced congestive heart failure. Each dose affected prompt but very short-lived increases in cardiac output and stroke work and decreases in pulmonary artery pressure, right atrial pressure and systemic and pulmonary vascular resistance in a non-dose-dependent fashion. Milrinone kinetics

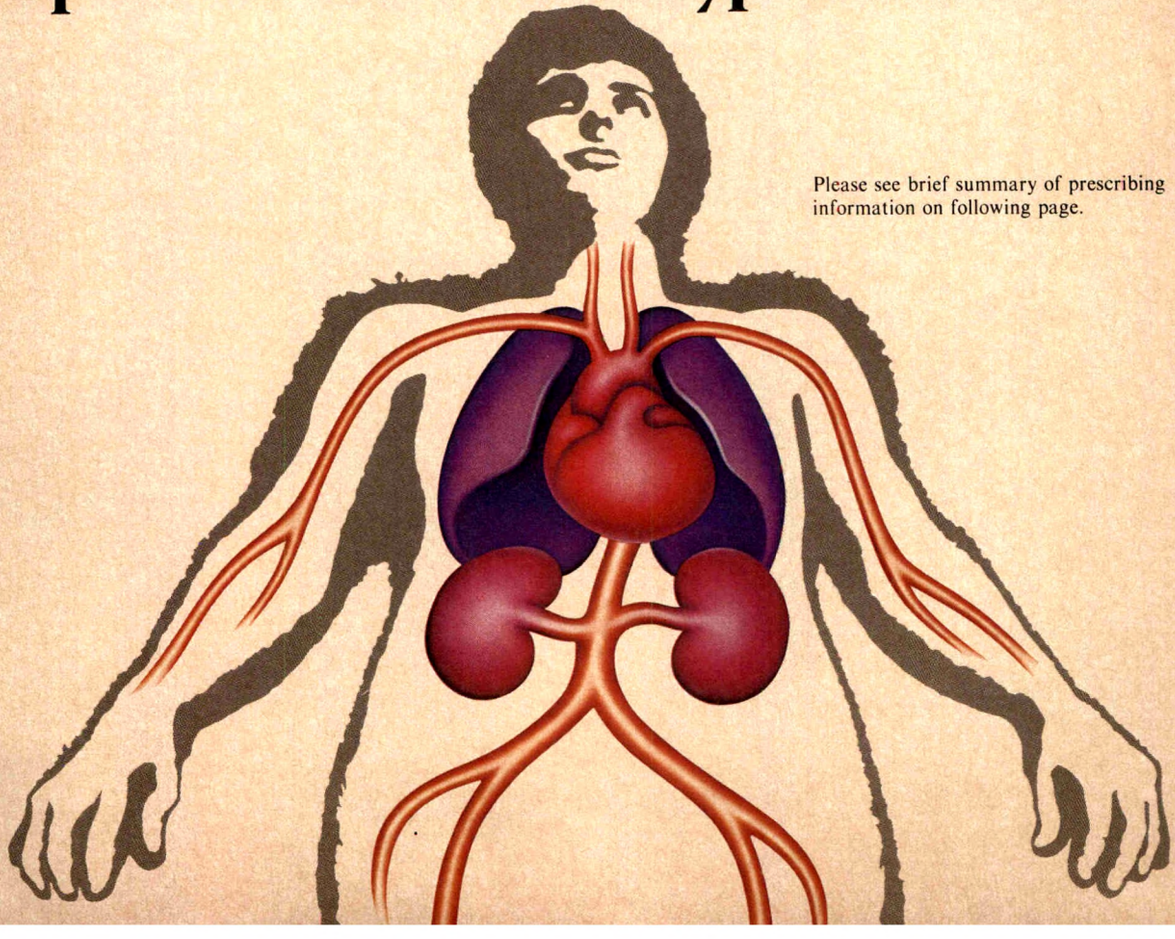
Schering

The unique single-entity blocker/dilator for hypertension

NORMODYNE®
Tablets (labetalol HCl)

Beyond beta blockers–also acts as a vasodilator to lower blood pressure.

Beyond vasodilators–acts as a beta blocker to blunt excessive cardiac response to exercise in hypertensives.



Please see brief summary of prescribing information on following page.

NORMODYNE®

brand of labetalol hydrochloride

Tablets

BRIEF SUMMARY

INDICATIONS AND USAGE

NORMODYNE (labetalol HCl) Tablets are indicated in the management of hypertension. NORMODYNE Tablets may be used alone or in combination with other antihypertensive agents, especially thiazide and loop diuretics.

CONTRAINDICATIONS

NORMODYNE (labetalol HCl) Tablets are contraindicated in bronchial asthma, overt cardiac failure, greater than first degree heart block, cardiogenic shock, and severe bradycardia (see **WARNINGS**).

WARNINGS

Cardiac Failure Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure. Beta blockade carries a potential hazard of further depressing myocardial contractility and precipitating more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, labetalol HCl can be used with caution in patients with a history of heart failure who are well-compensated. Congestive heart failure has been observed in patients receiving labetalol HCl. Labetalol HCl does not abolish the inotropic action of digitalis on heart muscle.

In Patients Without a History of Cardiac Failure In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, NORMODYNE (labetalol HCl) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal Angina pectoris has not been reported upon labetalol HCl discontinuation. However, hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered NORMODYNE (labetalol HCl), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, NORMODYNE (labetalol HCl) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue NORMODYNE (labetalol HCl) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis and emphysema) Patients with bronchospastic disease should, in general, not receive beta-blockers. NORMODYNE may be used with caution, however, in patients who do not respond to, or cannot tolerate, other antihypertensive agents. It is prudent, if NORMODYNE is used, to use the smallest effective dose, so that inhibition of endogenous or exogenous beta-agonists is minimized.

Pheochromocytoma Labetalol HCl has been shown to be effective in lowering the blood pressure and relieving symptoms in patients with pheochromocytoma. However, paradoxical hypertensive responses have been reported in a few patients with this tumor; therefore, use caution when administering labetalol HCl to patients with pheochromocytoma.

Diabetes Mellitus and Hypoglycemia Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; it may therefore be necessary to adjust the dose of antidiabetic drugs.

Major Surgery The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial. Protracted severe hypotension and difficulty in restarting or maintaining a heart beat have been reported with beta-blockers. The effect of labetalol HCl's alpha-adrenergic activity has not been evaluated in this setting.

A synergism between labetalol HCl and halothane anesthesia has been shown (see **Drug Interactions**).

PRECAUTIONS

General *Impaired Hepatic Function* NORMODYNE (labetalol HCl) Tablets should be used with caution in patients with impaired hepatic function since metabolism of the drug may be diminished.

Jaundice or Hepatic Dysfunction On rare occasions, labetalol HCl has been associated with jaundice (both hepatic and cholestatic). It is therefore recommended that treatment with labetalol HCl be stopped immediately should a patient develop jaundice or laboratory evidence of liver injury. Both have been shown to be reversible on stopping therapy.

Information for Patients

As with all drugs with beta-blocking activity, certain advice to patients being treated with labetalol HCl is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. While no incident of the abrupt withdrawal phenomenon (exacerbation of angina pectoris) has been reported with labetalol HCl, dosing with NORMODYNE Tablets should not be interrupted or discontinued without a physician's advice. Patients being treated with NORMODYNE Tablets should consult a physician at any sign of impending cardiac failure. Also, transient scalp tingling may occur, usually when treatment with NORMODYNE Tablets is initiated (see **ADVERSE REACTIONS**).

Laboratory Tests

As with any new drug given over prolonged periods, laboratory parameters should be observed over regular intervals. In patients with concomitant illnesses, such as impaired renal function, appropriate tests should be done to monitor these conditions.

Drug Interactions

In one survey, 2.3% of patients taking labetalol HCl in combination with tricyclic antidepressants experienced tremor as compared to 0.7% reported to occur with labetalol HCl alone. The contribution of each of the treatments to this adverse reaction is unknown but the possibility of a drug interaction cannot be excluded.

Drugs possessing beta-blocking properties can blunt the bronchodilator effect of beta-receptor agonist drugs in patients with bronchospasm; therefore, doses greater than the normal anti-asthmatic dose of beta-agonist bronchodilator drugs may be required.

Cimetidine has been shown to increase the bioavailability of labetalol HCl. Since this could be explained either by enhanced absorption or by an alteration of hepatic metabolism of labetalol HCl, special care should be used in establishing the dose required for blood pressure control in such patients.

Synergism has been shown between halothane anesthesia and intravenously administered labetalol HCl. During controlled hypotensive anesthesia using labetalol HCl in association with halothane, high concentrations (3% or above) of halothane should not be used because the degree of hypotension will be increased and because of the possibility of a large reduction in cardiac output and an increase in central venous pressure. The anesthesiologist should be informed when a patient is receiving labetalol HCl.

Labetalol HCl blunts the reflex tachycardia produced by nitroglycerin without preventing its hypotensive effect. If labetalol HCl is used with nitroglycerin in patients with angina pectoris, additional antihypertensive effects may occur.

Drug/Laboratory Test Interactions

The presence of a metabolite of labetalol in the urine may result in falsely increased levels of urinary catecholamines when measured by a nonspecific trihydroxyindole (THI) reaction. In screening patients suspected of having a pheochromocytoma and being treated with labetalol HCl, specific radioenzymatic or high performance liquid chromatography assay techniques should be used to determine levels of catecholamines or their metabolites.

Carcinogenesis, Mutagenesis, Impairment of Fertility

Long-term oral dosing studies with labetalol HCl for 18 months in mice and for 2 years in rats showed no evidence of carcinogenesis. Studies with labetalol HCl, using dominant lethal assays in rats and mice, and exposing microorganisms according to modified Ames tests, showed no evidence of mutagenesis.

Pregnancy Category C

Teratogenic studies have been performed with labetalol in rats and rabbits at oral doses up to approximately 6 and 4 times the maximum recommended human dose (MRHD), respectively. No reproducible evidence of fetal malformations was observed. Increased fetal resorptions were seen in both species at doses approximating the MRHD. There are no adequate and well-controlled studies in pregnant women. Labetalol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects

Infants of mothers who were treated with labetalol HCl for hypertension during pregnancy did not appear to be adversely affected by the drug. Oral administration of labetalol to rats during late gestation through weaning at doses of 2 to 4 times the MRHD caused a decrease in neonatal survival.

Labor and Delivery

Labetalol HCl given to pregnant women with hypertension did not appear to affect the usual course of labor and delivery.

Nursing Mothers

Small amounts of labetalol (approximately 0.004% of the maternal dose) are excreted in human milk. Caution should be exercised when NORMODYNE Tablets are administered to a nursing woman.

Pediatric Use

Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Most adverse effects are mild, transient and occur early in the course of treatment. In controlled clinical trials of 3 to 4 months duration, discontinuation of NORMODYNE (labetalol HCl) Tablets due to one or more adverse effects was required in 7% of all patients. In these same trials, beta-blocker control agents led to discontinuation in 8 to 10% of patients, and a centrally acting alpha-agonist in 30% of patients.

The incidence rates of adverse reactions listed in the following table were derived from multicenter controlled clinical trials, comparing labetalol HCl, placebo, metoprolol and propranolol, over treatment periods of 3 and 4 months. Where the frequency of adverse effects for labetalol HCl and placebo is similar, causal relationship is uncertain. The rates are based on adverse reactions considered probably drug-related by the investigator. If all reports are considered, the rates are somewhat higher (e.g., dizziness 20%, nausea 14%, fatigue 11%), but the overall conclusions are unchanged.

	Labetalol HCl (N = 227) %	Placebo (N = 98) %	Propranolol (N = 84) %	Metoprolol (N = 49) %
Body as a whole				
fatigue	5	0	12	12
asthenia	1	1	1	0
headache	2	1	1	2
Gastrointestinal				
nausea	6	1	1	2
vomiting	<1	0	0	0
dyspepsia	3	1	1	0
abdominal pain	0	0	1	2
diarrhea	<1	0	2	0
taste distortion	1	0	0	0
Central and Peripheral Nervous Systems				
dizziness	11	3	4	4
paresthesias	<1	0	0	0
drowsiness	<1	2	2	2
Autonomic Nervous System				
nasal stuffiness	3	0	0	0
ejaculation failure	2	0	0	0
impotence	1	0	1	3
increased sweating	<1	0	0	0

Special Senses				
vision abnormality	1	0	0	0
vertigo	2	1	0	0

The adverse effects were reported spontaneously and are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, i.e., a group excluding patients with bronchospastic disease, overt congestive heart failure or other contraindications to beta-blocker therapy.

Clinical trials also included studies utilizing daily doses up to 2400 mg in more severely hypertensive patients. Certain of the side effects increased with increasing dose as shown in the table below which depicts the entire U.S. therapeutic trials data base for adverse reactions that are clearly or possibly dose related.

Labetalol HCl Daily Dose (mg)	200	300	400	600
Number of Patients	522	181	606	608
Dizziness (%)	2	3	3	3
Fatigue	2	1	4	4
Nausea	<1	0	1	2
Vomiting	0	0	<1	<1
Dyspepsia	1	0	2	1
Paresthesias	2	0	2	2
Nasal Stuffiness	1	1	2	2
Ejaculation Failure	0	2	1	2
Impotence	1	1	1	1
Edema	1	0	1	1

Labetalol HCl Daily Dose (mg)	800	900	1200	1600	2400
Number of Patients	503	117	411	242	175
Dizziness (%)	5	1	9	13	16
Fatigue	5	3	7	6	10
Nausea	4	0	7	11	19
Vomiting	<1	0	1	2	3
Dyspepsia	1	0	2	2	4
Paresthesias	1	1	2	5	5
Nasal Stuffiness	2	2	4	5	6
Ejaculation Failure	3	0	4	3	5
Impotence	2	4	3	4	3
Edema	1	0	1	2	2

In addition, a number of other less common adverse events have been reported in clinical trials or the literature:

Cardiovascular Postural hypotension, including rarely, syncope.

Central and Peripheral Nervous Systems Paresthesias, most frequently described as scalp tingling. In most cases, it was mild, transient and usually occurred at the beginning of treatment.

Collagen Disorders Systemic lupus erythematosus; positive antinuclear factor (ANF).

Eyes Dry eyes.

Immunological System Antimitochondrial antibodies.

Liver and Biliary System Cholestasis with or without jaundice.

Musculo-Skeletal System Muscle cramps; toxic myopathy.

Respiratory System Bronchospasm.

Skin and Appendages Rashes of various types, such as generalized maculo-papular lichenoid; urticarial; bullous lichen planus; psoriaform; facial erythema; Peyronie's disease; reversible alopecia.

Urinary System Difficulty in micturition, including acute urinary bladder retention.

Following approval for marketing in the United Kingdom, a monitored release survey involving approximately 6,800 patients was conducted for further safety and efficacy evaluation of this product. Results of this survey indicate that the type, severity, and incidence of adverse effects were comparable to those cited above.

Potential Adverse Effects

In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents.

Central Nervous System Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular Intensification of AV block. See **CONTRAINDICATIONS.**

Allergic Fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic Agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura.

Gastrointestinal Mesenteric artery thrombosis; ischemic colitis.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with labetalol HCl.

Clinical laboratory tests: There have been reversible increases of serum transaminases in 4% of patients treated with labetalol HCl and tested, and more rarely, reversible increases in blood urea.

OVERDOSAGE

Overdosage with NORMODYNE (labetalol HCl) Tablets causes excessive hypotension which is posture sensitive, and sometimes, excessive bradycardia. Patients should be laid supine and their legs raised if necessary to improve the blood supply to the brain. The following additional measures should be employed if necessary: *Excessive bradycardia* — administer atropine (3.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously. *Cardiac failure* — administer a digitalis glycoside and a diuretic. *Hypotension* — administer vasopressors, e.g., norepinephrine. There is pharmacological evidence that norepinephrine may be the drug of choice. *Bronchospasm* — administer a beta$_2$-stimulating agent and/or a theophylline preparation.

Gastric lavage or pharmacologically induced emesis (using syrup of ipecac) is useful for removal of the drug shortly after ingestion. Labetalol HCl can be removed from the general circulation by hemodialysis.

The oral LD_{50} value of labetalol HCl in the mouse is approximately 600 mg/kg and in the rat is greater than 2 gm/kg. The intravenous LD_{50} in these species is 50 to 60 mg/kg.

DOSAGE AND ADMINISTRATION

DOSAGE MUST BE INDIVIDUALIZED. The recommended initial dose is 100 mg twice daily whether used alone or added to a diuretic regimen. After 2 or 3 days, using standing blood pressure as an indicator, dosage may be titrated in increments of 100 mg bid every 2 or 3 days. The usual maintenance dosage of labetalol HCl is between 200 and 400 mg twice daily.

Since the full antihypertensive effect of labetalol HCl is usually seen within the first one to three hours of the initial dose or dose increment, the assurance of a lack of an exaggerated hypotensive response can be clinically established in the office setting. The antihypertensive effects of continued dosing can be measured at subsequent visits, approximately 12 hours after a dose, to determine whether further titration is necessary.

Patients with severe hypertension may require from 1200 mg to 2400 mg per day, with or without thiazide diuretics. Should side effects (principally nausea or dizziness) occur with these doses administered bid, the same total daily dose administered tid may improve tolerability and facilitate further titration. Titration increments should not exceed 200 mg bid.

When a diuretic is added, an additive antihypertensive effect can be expected. In some cases this may necessitate a labetalol HCl dosage adjustment. As with most antihypertensive drugs, optimal dosages of NORMODYNE Tablets are usually lower in patients also receiving a diuretic.

When transferring patients from other antihypertensive drugs, NORMODYNE Tablets should be introduced as recommended and the dosage of the existing therapy progressively decreased.

HOW SUPPLIED

NORMODYNE (labetalol HCl) Tablets, 100 mg, light-brown, round, scored, film-coated tablets engraved on one side with Schering and product identification numbers 244, and on the other side the number 100 for the strength and "NORMODYNE"; bottles of 100 (NDC-0085-0244-04), 500 (NDC-0085-0244-05), and box of 100 for unit-dose dispensing (NDC-0085-0244-08).

NORMODYNE (labetalol HCl) Tablets, 200 mg, white, round, scored, film-coated tablets engraved on one side with Schering and product identification numbers 752, and on the other side the number 200 for the strength and "NORMODYNE"; bottles of 100 (NDC-0085-0752-04), 500 (NDC-0085-0752-05), box of 100 for unit-dose dispensing (NDC-0085-0752-08), and Patient Calendar Package of 56 (4 bottles of 14 tablets) (NDC-0085-0752-03).

NORMODYNE (labetalol HCl) Tablets, 300 mg, blue, round, film-coated tablets engraved on one side with Schering and product identification numbers 438, and on the other side the number 300 for the strength and "NORMODYNE"; bottles of 100 (NDC-0085-0438-03), 500 (NDC-0085-0438-05), box of 100 for unit-dose dispensing (NDC-0085-0438-06), and Patient Calendar Package of 56 (4 bottles of 14 tablets) (NDC-0085-0438-02).

NORMODYNE (labetalol HCl) Tablets should be stored between 2° and 30°C (36° and 86°F).

NORMODYNE (labetalol HCl) Tablets in the unit-dose boxes should be protected from excessive moisture.

CLINICAL STRESS TESTING AT ITS BEST.

THE JUSTIFIABLE SYSTEM...

When your clinical needs dictate a sophisticated *and* cost-efficient diagnostic system for performing stress tests, Quinton's Q2000 System is the answer.

With the Q2000, you get:

- Powerful multi-processor hardware.
- Fast and accurate software analysis.
- Programmable flexibility.
- Diagnostic quality output.
- Long-term reliability.

PROGRAMMABILITY...

The easy-to-operate Q2000 enables you to program, modify and access up to 5 environments (procedures) and 9 protocols having up to 26 stages each.

THE DIAGNOSTIC EDGE...

ST Integral and Index, in addition to ST Slope and Level, provide higher sensitivity and specificity than slope and level alone. Your diagnostic confidence in tests that may otherwise produce marginal results is improved.

Also:

- Absolute Spatial Vector Velocity (ASVV) is used to identify aberrant beats, align normal beats for signal averaging and establish the isoelectric point.
- ST parameters may be measured from either J-junction or R-wave peak, and you program the measurement criteria.

The Q55 TREADMILL is included and provides 350-lb. patient capacity, 1–10 mph speed range, 0–25% grade range, and automatic calibration, self-test and trouble monitoring.

OTHER FEATURES...

- COMPREHENSIVE DISPLAYS—6 seconds of live ECG data, resting and current averaged beats, split screen freeze, tabular and graphic displays, continuous write from memory, digital displays of heart rate, ST parameters, and stage and time data.
- THERMAL CHART RECORDER—Programmable operation, AHA diagnostic quality traces, computer-averaged beats available.
- FINAL REPORT—An automatic summary of your patient's test data saves valuable time in report preparation.
- SERVICE AND MAINTENANCE—Fast response and the built-in maintenance programs keep the service call short.

For a detailed brochure, examples of ECG printouts and reports, and cost analysis information, call or write Quinton Instrument Company, 2121 Terry Avenue, Seattle, WA 98121-2791. 1-800-426-0347. Telex 3794094 In Washington state and Canada, call (206) 223-7373.

Clinical Clues to MIXED ANGINA *No. 1*

Thirty seconds ago he was reading

He wasn't exercising; his myocardial oxygen demand didn't increase. Yet now he's having an angina attack.

That's the unpredictability of MIXED ANGINA—vasoconstriction coexisting with fixed coronary lesion, to produce a critical reduction of myocardial blood flow.

And because vasoconstriction is an unpredictable event, ischemia and pain occur unpredictably:

- at rest, or even during sleep
- at varying levels of exercise
- upon exposure to cold
- under emotional stress
- diurnally, typically in the morning

PROCARDIA® (nifedipine) is a primary therapy for the patient with MIXED ANGINA. It prevents vasoconstriction in both large coronary arteries and coronary arterioles to maintain myocardial blood flow and oxygen supply. At the same time, PROCARDIA dilates peripheral arteries to reduce afterload and myocardial oxygen demand.

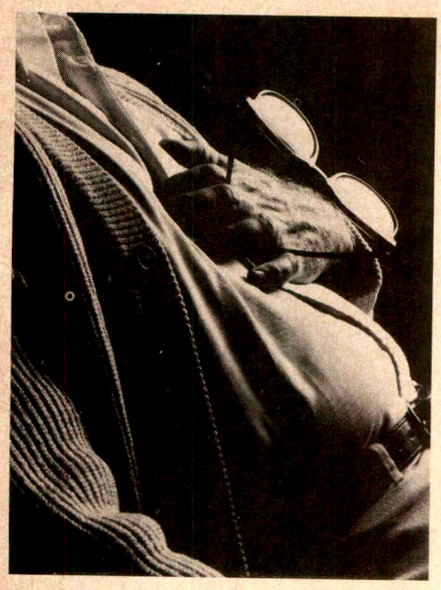
As a result, PROCARDIA can significantly reduce your patient's angina attack rate and need for nitroglycerin.[1]

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

Primary Protection in
MIXED ANGINA

Please see PROCARDIA® (nifedipine) brief summary on next page.

Thirty seconds ago he was reading.



PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

PRIMARY PROTECTION IN MIXED ANGINA

Usual Effective Dosage: 30 to 60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because PROCARDIA decreases peripheral vascular resistance (occasional patients have had excessive hypotension), careful monitoring of blood pressure during initial administration and upward dosage titration is suggested, especially for patients taking drugs known to lower blood pressure. Occasional patients have developed increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases.

A Favorable Safety Profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

1. Stone PH, Muller JE, Turi ZG, et al: Efficacy of nifedipine therapy in patients with refractory angina pectoris: Significance of the presence of coronary vasospasm. *Am Heart J* 106:644-652, 1983.

Brief Summary
PROCARDIA® (nifedipine) Capsules For Oral Use

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See WARNINGS.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina: Occasional patients have developed well-documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See WARNINGS.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Laboratory tests: Rare, usually transient, but occasionally significant elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT and SGPT have been noted. The relationship to PROCARDIA (nifedipine) therapy is uncertain in most cases, but probable in some. These laboratory abnormalities have rarely been associated with clinical symptoms, however, cholestasis with or without jaundice has been reported. Rare instances of allergic hepatitis have been reported.

Limited clinical studies have demonstrated a moderate but statistically significant decrease in platelet aggregation and increase in bleeding time in some PROCARDIA patients. No clinical significance for these findings has been demonstrated.

Although PROCARDIA has been used safely in patients with renal dysfunction and has been reported to exert a beneficial effect in certain cases, rare, reversible elevations in BUN and serum creatinine have been reported in patients with pre-existing chronic renal insufficiency. The relationship to PROCARDIA therapy is uncertain in most cases but probable in some.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Coumarin anticoagulants: There have been rare reports of increased prothrombin time in patients taking coumarin anticoagulants to whom PROCARDIA was administered.

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak nifedipine plasma levels (80%) and area-under-the-curve (74%) after a one week course of cimetidine at 1000 mg per day and nifedipine at 40 mg per day. Ranitidine produced smaller, non-significant increases. If nifedipine therapy is initiated in a patient currently receiving cimetidine, cautious titration is advised.

Carcinogenesis, mutagenesis, impairment of fertility: Nifedipine was administered orally to rats for two years and was not shown to be carcinogenic. When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose. *In vivo* mutagenicity studies were negative.

Pregnancy: Pregnancy Category C. Nifedipine has been shown to be teratogenic in rats and embryotoxic in rats, mice and rabbits. There are no adequate and well controlled studies in pregnant women. PROCARDIA should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: The most common adverse events include dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, shortness of breath, diarrhea, constipation, gastrointestinal cramps, flatulence, inflammation, joint stiffness, shakiness, jitteriness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, sexual difficulties, thrombocytopenia, anemia, leukopenia, purpura, allergic hepatitis, gingival hyperplasia, and erythromelalgia. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related: Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

conformed to an open 2-compartment model of drug distribution and elimination. The elimination half-life of milrinone is such that bolus administration is required for rapid hemodynamic efficacy. However, hemodynamic effects should resolve promptly with discontinuation of milrinone therapy.

690 **Effects of Hydralazine on Pressure-Volume and Stress-Volume Relations in Congestive Heart Failure Secondary to Idiopathic Dilated Cardiomyopathy**
MARK L. SMUCKER, C. FAGG SANFORD, and KIRK M. LIPSCOMB

The mechanism by which hydralazine improves cardiac function in patients with heart failure is not well characterized. Hydralazine may improve left ventricular (LV) function by decreasing afterloading LV wall stress or by increasing myocardial contractility. The effect of intravenous hydralazine was assessed in 8 patients with severe idiopathic dilated cardiomyopathy. Hydralazine increased stroke volume index and ejection fraction and decreased systemic vascular resistance and LV stress. Patients with high LV wall stress had higher LV end-diastolic pressure, higher LV end-diastolic volume index, lower ejection fraction and higher systemic vascular resistance than patients with normal LV stress. LV wall stress decreased more in patients with high LV stress, because hydralazine decreased systolic pressure and diastolic pressure or volume in those patients. Late systolic portions of pressure-volume loops in patients with normal LV stress suggested increased myocardial contractility, but this was not confirmed by LV dP/dt. Hydralazine improves LV function in patients with dilated cardiomyopathy by reducing elevated LV wall stress.

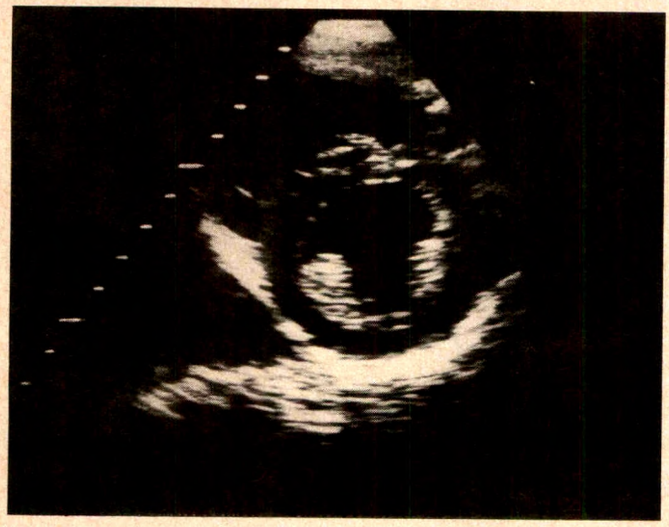
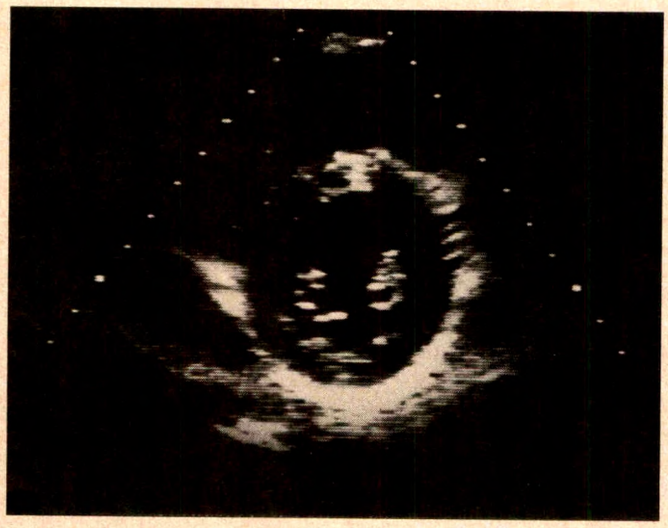
The only difference in Cardioscan's image is the cost.



$25,000 Cardioscan's affordable image looks like this.



$90,000 At more than three times the cost of Cardioscan, their image looks the same.

Until now, sophisticated, high-resolution echocardiography came with a high price tag. To get images like the one at the top you had to pay the cost at the bottom. Interspec has changed all that. We developed Cardioscan™—the easy-to-use echocardiography system that makes high-quality ultrasound imaging not only possible, but *affordable.*

Unlike other low-cost systems, Cardioscan doesn't sacrifice performance for price. You get all the advantages of larger, hospital-scale units—plus, some features often not available even on more expensive systems.

And, Cardioscan has been designed with the future in mind. You do not have to be concerned about your system becoming obsolete as echocardiographic technology advances or your clinical needs change. Your system will be fully upgradeable to keep pace with the demands of your practice.

The best technology packaged in a lightweight, compact design

There is only one way to understand the quality Cardioscan delivers. And that is to compare it with other units. Even when judged against systems costing three times as much, Cardioscan more than measures up.

More reasons to decide on Cardioscan

- Superior image quality and resolution in both 2-D and M-mode.
- Logically grouped, easy-to-learn controls let you concentrate on the patient, not the instrument.
- On-line or off-line calculations capability means calculations and annotations can be performed during patient examinations, or later *in video playback.*
- Triple image memory means you can store up to three images and select the preferred one for calculations and/or hard copy.

- ECG with dual trigger enables automatic viewing of end-systolic and end-diastolic images from the same cardiac cycle.
- Small, lightweight transducer available in a variety of frequencies and focal zones helps make Cardioscan adaptable to a wide range of applications.

The Cardioscan Doppler

In keeping with Interspec's commitment to cardiology, Cardioscan has been designed to accept major upgrades. One of the first of these is the Cardioscan Doppler, which adds noninvasive hemodynamics to your diagnostic capabilities. With pulsed, high PRF, continuous wave and comprehensive calculations, this Doppler is truly state-of-the-art.

Reliable service

Because Cardioscan is made in the U.S., availability of parts is never a problem. A complete service policy includes rapid response to calls and a loaner program to assure maximum up-time.

Compare our image. Compare our price.
Compare our features.

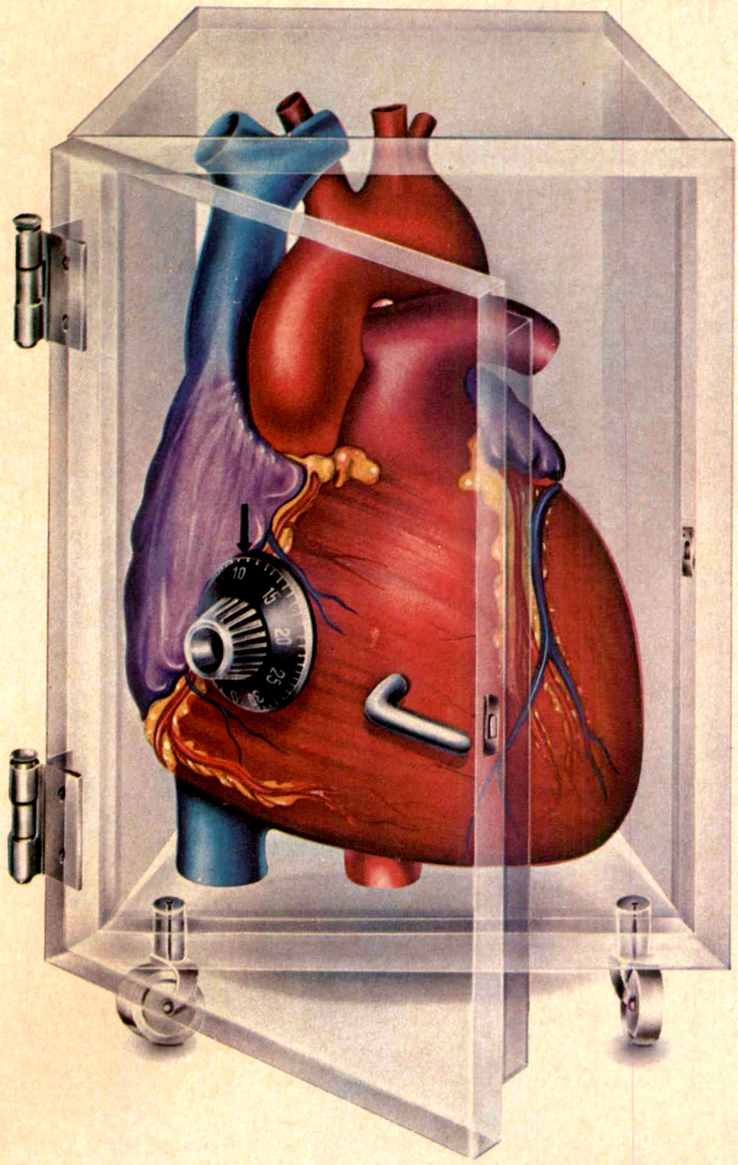
In hypertension... the risks of some diuretics or the protection of Lopressor



Safe from complications due to diuretic-induced K+loss

Unlike some diuretics, Lopressor does not waste potassium or cause hypokalemia which has been implicated in cardiac arrhythmias. Some diuretic therapy requires professional monitoring for potassium depletion.

Excellent safety record

Lopressor is generally well tolerated. Shortness of breath and bradycardia have occasionally been reported. Cardioselectivity* offers an added margin of safety compared to nonselective beta blockers.

A safe bet for compliance

The combination of once-a-day dosage and good tolerability makes a Lopressor regimen easy for patients to stay with.

*Exerts a relative preference for beta-one receptors; this preference is not absolute.

Contraindicated in heart block greater than first degree, sinus bradycardia, cardiogenic shock, and overt heart failure. Side effects with Lopressor are generally mild and transient, the most common being tiredness, dizziness, depression, and diarrhea.

Please see next page for Brief Summary of Prescribing Information.

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE
Hypertension
Lopressor tablets are indicated for the treatment of hypertension. They may be used alone or in combination with other antihypertensive agents.
Myocardial Infarction
Lopressor ampuls, prefilled syringes and tablets are indicated in the treatment of hemodynamically stable patients with definite or suspected acute myocardial infarction to reduce cardiovascular mortality. Treatment with intravenous Lopressor can be initiated as soon as the patient's clinical condition allows (see **DOSAGE AND ADMINISTRATION, CONTRAINDICATIONS,** and **WARNINGS**). Alternatively, treatment can begin within 3 to 10 days of the acute event (see **DOSAGE AND ADMINISTRATION**).

CONTRAINDICATIONS
Hypertension
Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **WARNINGS**).
Myocardial Infarction
Lopressor is contraindicated in patients with a heart rate < 45 beats/min; significant heart block greater than first degree (P-R interval ≥ 0.24 sec); systolic blood pressure < 100 mmHg; or moderate-to-severe cardiac failure (see **WARNINGS**).

WARNINGS
Hypertension
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and Lopressor slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic. The response should be observed closely. If cardiac failure continues, despite adequate digitalization and diuretic therapy, Lopressor should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice (see **PRECAUTIONS, Information for Patients**).

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly, and the lowest possible dose of Lopressor should be used. In these circumstances it would be prudent initially to administer Lopressor in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See DOSAGE AND ADMINISTRATION.)**

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial; the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Lopressor, like other beta blockers, is a competitive inhibitor of beta-receptor agonists, and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes and Hypoglycemia: Lopressor should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade, which might precipitate a thyroid storm.

Myocardial Infarction
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function, and beta blockade carries the potential hazard of depressing myocardial contractility and precipitating or exacerbating minimal cardiac failure.

During treatment with Lopressor, the hemodynamic status of the patient should be carefully monitored. If heart failure occurs or persists despite appropriate treatment, Lopressor should be discontinued.

Bradycardia: Lopressor produces a decrease in sinus heart rate in most patients; this decrease is greatest among patients with high initial heart rates and least among patients with low initial heart rates. Acute myocardial infarction (particularly inferior infarction) may in itself produce significant lowering of the sinus rate. If the sinus rate decreases to < 40 beats/min, particularly if associated with evidence of lowered cardiac output, atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, Lopressor should be discontinued, and cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

AV Block: Lopressor slows AV conduction and may produce significant first- (P-R interval ≥0.26 sec), second-, or third-degree heart block. Acute myocardial infarction also produces heart block.

If heart block occurs, Lopressor should be discontinued and atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

Hypotension: If hypotension (systolic blood pressure ≤ 90 mmHg) occurs, Lopressor should be discontinued, and the hemodynamic status of the patient and the extent of myocardial damage carefully assessed. Invasive monitoring of central venous, pulmonary capillary wedge, and arterial pressures may be required. Appropriate therapy with fluids, positive inotropic agents, balloon counterpulsation, or other treatment modalities should be instituted. If hypotension is associated with sinus bradycardia or AV block, treatment should be directed at reversing these (see above).

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, Lopressor may be used with extreme caution in patients with bronchospastic disease. Because it is unknown to what extent beta$_2$-stimulating agents may exacerbate myocardial ischemia and the extent of infarction, these agents should *not* be used prophylactically. If bronchospasm not related to congestive heart failure occurs, Lopressor should be discontinued. A theophylline derivative or a beta$_2$ agonist may be administered cautiously, depending on the clinical condition of the patient. Both theophylline derivatives and beta$_2$ agonists may produce serious cardiac arrhythmias.**

PRECAUTIONS
General
Lopressor should be used with caution in patients with impaired hepatic function.
Information for Patients
Patients should be advised to take Lopressor regularly and continuously, as directed, with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Lopressor without consulting the physician.

Patients should know how they react to this medicine before they operate automobiles and machinery or engage in other tasks requiring alertness. Patients should contact the physician if any difficulty in breathing occurs, and before surgery of any type, the patient should inform the physician or dentist that he or she is taking Lopressor.
Laboratory Tests
Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.
Drug Interactions
Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.
Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a 1-year study in dogs, there was no evidence of drug-induced toxicity at or below oral dosages of 105 mg/kg per day. In 2-year studies in rats at three oral dosage levels of up to 800 mg/kg per day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dosage levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.
Pregnancy Category B
Reproduction studies have been performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg and have revealed no evidence of impaired fertility or teratogenicity due to Lopressor. Increased postimplantation loss and decreased neonatal survival did occur in the rats (threshold between 50 and 500 mg/kg), and distribution studies in mice confirm exposure of the fetus when Lopressor is administered to the pregnant animal. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers
Lopressor is excreted in breast milk in very small quantity. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Lopressor is administered to a nursing woman.
Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Hypertension
Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression has been reported in about 5 of 100 patients. Mental confusion and short-term memory loss have been reported. Headache, nightmares, and insomnia have also been reported, but a drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations; and congestive heart failure have been reported. (See **CONTRAINDICATIONS, WARNINGS,** and **PRECAUTIONS**.)

Respiratory: Wheezing (bronchospasm) has been reported in fewer than 1 of 100 patients (see **WARNINGS**).

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100, or fewer, patients.

Hypersensitive Reactions: Pruritus has occurred in fewer than 1 of 100 patients. Rash has been reported.

Miscellaneous: Peyronie's disease has been reported in fewer than 1 of 100,000 patients. Alopecia has been reported.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor.
Myocardial Infarction
Central Nervous System: Tiredness has been reported in about 1 of 100 patients. Vertigo, sleep disturbances, hallucinations, headache, dizziness, visual disturbances, confusion, and reduced libido have also been reported, but a drug relationship is not clear.

Cardiovascular: In the randomized comparison of Lopressor and placebo described in the **CLINICAL PHARMACOLOGY** section, the following adverse reactions were reported:

	Lopressor	*Placebo*
Hypotension (systolic BP < 90 mmHg)	27.4%	23.2%
Bradycardia (heart rate < 40 beats/min)	15.9%	6.7%
Second- or third-degree heart block	4.7%	4.7%
First-degree heart block (P-R ≥ 0.26 sec)	5.3%	1.9%
Heart failure	27.5%	29.6%

Respiratory: Dyspnea of pulmonary origin has been reported in fewer than 1 of 100 patients.

Gastrointestinal: Nausea and abdominal pain have been reported in fewer than 1 of 100 patients.

Dermatologic: Rash and worsened psoriasis have been reported, but a drug relationship is not clear.

Miscellaneous: Unstable diabetes and claudication have been reported, but a drug relationship is not clear.
Potential Adverse Reactions
A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Lopressor.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

Simultaneous Computer Mapping to Facilitate Intraoperative Localization of Accessory Pathways in Patients with Wolff-Parkinson-White Syndrome

JEFFREY B. KRAMER, MD, PETER B. CORR, PhD, JAMES L. COX, MD, FRANCIS X. WITKOWSKI, MD, and MICHAEL E. CAIN, MD

Sixteen patients with the Wolff-Parkinson-White syndrome underwent simultaneous intraoperative computer mapping from multiple sites before surgical division of the accessory pathways. A 16-bipolar electrode band was positioned around the atrioventricular groove. Ventricular epicardial electrograms from single beats were recorded simultaneously during atrial pacing, resulting in maximal preexcitation, and atrial electrograms were recorded during orthodromic supraventricular tachycardia. Four-level transmural plunge needle electrodes were used concomitantly in 3 patients. Electrograms were processed separately using a guarded signal conditioner that isolates, amplifies, filters and analog-to-digitally converts synchronously at 2 kHz with 12-bit accuracy. Digital data were transmitted by fiber optics to a high-density digital recorder and processed with a computer having rapid interactive graphics. Results in the 16 patients revealed 20 distinct Kent bundles. Two patients had only nonsustained supraventricular tachycardia induced intraoperatively and 1 patient manifested intermittent anterograde ventricular preexcitation. Multiple pathways were identified in 4 patients. This simultaneous multiple electrode mapping procedure facilitates intraoperative mapping by requiring only a single beat for analysis of anterograde and retrograde activation times, decreases cardiac manipulation during mapping and obviates the need for cardiopulmonary bypass, and permits analysis of transmural activation patterns. This approach decreases markedly the time required for mapping and permits accurate study of nonsustained arrhythmias as well as rapid identification of multiple accessory pathways.

Surgical division of accessory atrioventricular (AV) pathways has been shown to be effective and safe for the treatment of symptomatic patients with the Wolff-Parkinson-White syndrome.[1–4] The success of surgical therapy depends on accurate localization of the accessory pathway. Intraoperative mapping is performed to define precisely the atrial and ventricular insertion sites of the accessory pathways and to detect additional accessory pathways that may not have been readily apparent preoperatively. Conventional intraoperative mapping procedures involve the sequential assessment

of ventricular and atrial epicardial activation patterns by a single-bipolar probe during stable ventricular preexcitation and sustained orthodromic supraventricular tachycardia, (SVT), respectively.[5–7] The conventional approach has been limited by the time required to complete mapping and the associated hemodynamic compromise that often accompanies induction of SVT, necessitating prolonged cardiopulmonary bypass time and the requirement of a uniform sustained arrhythmia. In addition, extensive cardiac manipulation, particularly during mapping of the posterior aspect of the heart, may result in a change in QRS and delta wave configuration, further hemodynamic embarrassment and inability to maintain a sustained SVT.

Recently, we developed a computerized mapping system that allows for simultaneous acquisition, storage and analysis of multiple epicardial, intramural and endocardial electrograms derived from a single depolarization of the heart.[8] To obviate the limitations of conventional procedures, we performed simultaneous computer mapping intraoperatively in patients with Wolff-Parkinson-White (WPW) syndrome referred for surgical treatment. We first selected patients with WPW syndrome to assess the clinical applicability of the computer mapping system, since the pathogenesis of this disorder has been well characterized.

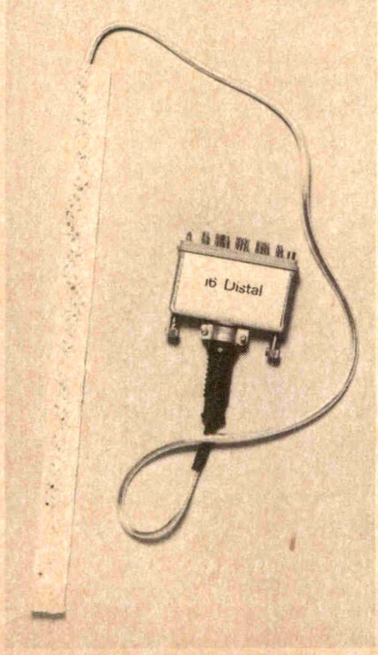

FIGURE 1. Epicardial band containing 16 bipolar button electrodes.

Methods

Patients: Sixteen patients with WPW syndrome referred to Barnes Hospital for surgical division of their accessory pathways were studied intraoperatively with the computer mapping system. Each patient had recurrent episodes of sustained orthodromic SVT, atrial fibrillation, or both. Each patient was studied preoperatively in the Barnes Hospital Electrophysiology Laboratory using standard catheter techniques.[9] Pertinent clinical characteristics of the patients are summarized in Table I. Eighteen accessory pathways were identified in the 16 patients during the preoperative electrophysiology study. Two additional pathways were identified during computer mapping intraoperatively.

Mapping procedure: Computer mapping was performed in each patient after induction of anesthesia, exposure of the heart through a median sternotomy and cannulation of the great vessels, but before institution of cardiopulmonary bypass. A nylon mesh band with 16 bipolar button electrodes (Fig. 1) was positioned around the AV groove. The electrode buttons had an interpole spacing of 0.6 mm and rested lightly on the epicardial surface of the heart. The distance between electrode buttons was 1 cm. Positioning of the band required only minimal cardiac manipulation and, once moist, remained adherent to the epicardium. Anterograde ventricular activation was assessed first during maximal ventricular preexcitation with the band array located below the anular fibrosis. Pacing from the atrium ipsilateral to the accessory pathway was used to facilitate preexcitation. Decisions regarding pacing site and rate of pacing were based on results of the preoperative electrophysiology study. If multiple pathways were suspected preoperatively or intraoperatively, pacing from multiple atrial sites was performed and anterograde ventricular activation assessed. The electrode band was moved superiorly to the atrium. Retrograde atrial activation was then assessed during orthodromic SVT. In 1 patient, only isolated AV echo beats were observed intraoperatively and sustained orthodromic SVT could not be induced. Mapping from multiple atrial sites simultaneously was performed during isolated AV echo beats. After institution of cardiopulmonary bypass, single-probe mapping was performed in the first 4 patients to confirm the findings of the computer analysis and in 5 patients who had posterior septal pathways as an adjunctive technique for endocardial mapping. In 3 patients who had left free wall pathways localized by the band technique, 4 plunge needle electrodes containing 4 bipolar pairs per needle were inserted at the site of the ventricular insertion of the accessory pathway and on either side of the anomalous connection. Interpole spacing was 500 μm and each bipole was separated by 2.5 mm, with the proximal bipole pair located 500 μm from the epicardial surface. The transmural pattern of ventricular activation was assessed during a maximally preexcited beat.

Data processing and analysis: The computer system used was recently described in detail.[8] The system was designed to accumulate simultaneous information from multiple intracardiac locations and to facilitate rapid and accurate analysis of the data.

Bipolar electrogram information obtained from epicardial and intramural electrodes, along with electrocardiographic data, were sampled at 2 kHz, individually amplified, filtered (40 to 500 Hz), and digitized using a portable operating room cart specially designed for this purpose. The output of each amplifier was sequentially strobed at 500 kHz, converted from parallel to serial and transferred in a 12-bit digital format through a fiberoptic digital transmission system to the remote computer facility located approximately 1,000 yards from the

operating suite. The data were then converted back from a serial to parallel format and stored on a Sangamo-Weston Sabre IV high-density recorder, from which desired data segments were analyzed. A 2-way audio transmission and analog electrocardiographic data also accompanied the digital data stream from the operating room to the computer facility.

Data analysis was performed in several automated steps using a PDP 11/34A (Digital Equipment Corp.) computer equipped with high-resolution graphic capabilities. Once the appropriate beats had been recorded, the electrocardiogram was scanned and a time window of variable length chosen to examine depolarization sequences of interest. During assessment of anterograde ventricular activation, the time window was positioned at the onset of the delta wave and incorporated the QRS complex. During assessment of retrograde atrial activation during either sustained orthodromic SVT or an AV echo beat the time window was positioned at the end of the QRS complex and incorporated the retrograde P wave. Each electrogram was autocalibrated and displayed along with a computer-chosen activation time based on a peak criterion.[6,10] Earliest sites of activity and their relation to the delta wave or retrograde P wave were used to pinpoint ventricular and atrial insertion sites of the Kent fibers, respectively. The electrographic information and activation times were available instantaneously in the operating room, which was equipped with a color graphic display similar to that located in the computer facility.

Results

Simultaneous intraoperative computer mapping facilitated accurate localization of accessory pathways and afforded several other advantages over conventional procedures. A representative retrograde atrial activation map during orthodromic SVT is shown in Figure 2. Earliest retrograde atrial activation occurred 27 ms after the beginning of the time window and was located at a left posterolateral site. The remaining sites are activated in a sequential, orderly fashion confirming the presence of a single accessory pathway.

Single probe epicardial mapping was performed in the first 4 patients to validate activation patterns determined using the computer mapping system. In these

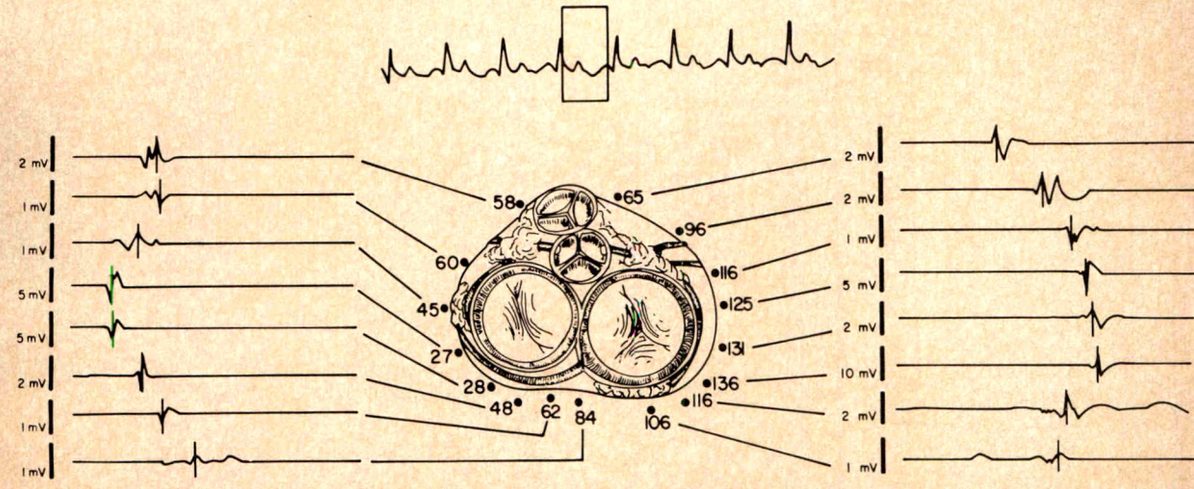

FIGURE 2. Retrograde atrial epicardial activation times during sustained orthodromic supraventricular tachycardia. The electrocardiogram, time window and atrial epicardial electrograms are shown. **Numbers** on the **left** of each recording refer to a peak-to-peak amplitude scale after autoranging of the individual electrograms. The **vertical cursor** represents the computer-derived activation time at each electrode site. In this example, a single left free wall pathway is apparent. Earliest atrial activity was recorded 27 ms after the onset of the time window.

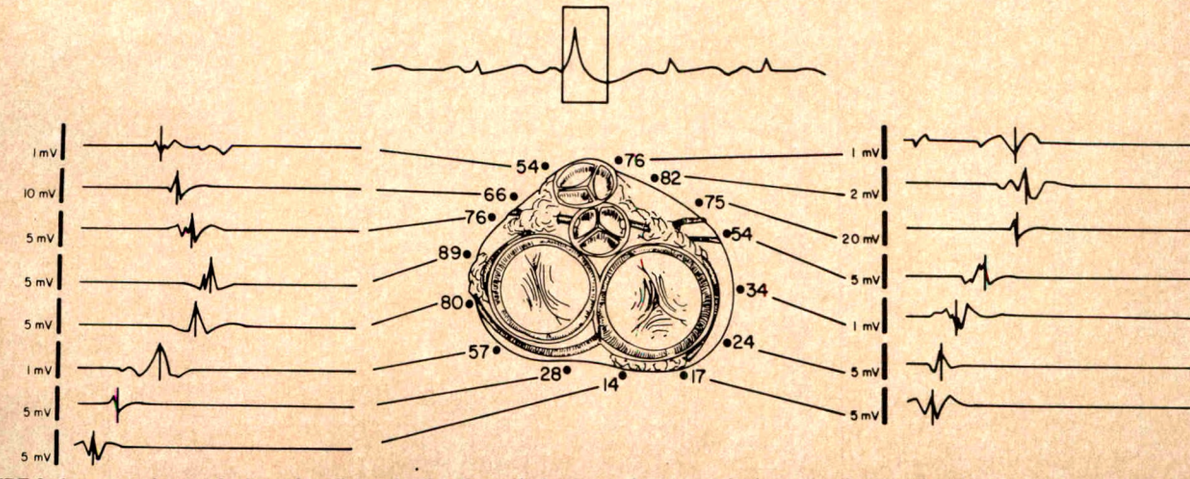

FIGURE 3. Anterograde ventricular epicardial activation times during intermittent ventricular preexcitation. The electrocardiogram shows a single preexcited beat. The activation map indicates the presence of a right-sided paraseptal bypass tract.

patients, the results of the single hand-held probe study localized the accessory pathway to the same site identified by the computer mapping system. However, the conventional approach required cardiopulmonary bypass, prolonged atrial pacing and sustained orthodromic SVT, considerable cardiac manipulation, and 30 to 40 minutes to acquire and accurately analyze the data.

During computer mapping, however, only a single beat of the SVT was required for atrial activation times. As a result, the episode of SVT was terminated after only several beats, obviating the need for cardiopulmonary bypass during the mapping procedure. Complete atrial and ventricular mapping and data analysis can be completed in approximately 10 minutes.

Accurate localization of accessory pathways manifesting intermittent conduction has heretofore been difficult and frequently impossible. Simultaneous mapping, in which localization can be made on the basis of a single beat, obviates this difficulty. Figure 3 shows intermittent ventricular preexcitation. Simultaneous mapping of multiple ventricular sites around the AV groove during a single preexcited beat reveals a right posterior paraseptal pathway activating 14 ms after the onset of the time window. A second relatively early zone of activation observed anteriorly (54 ms) is most likely the result of anterograde conduction through the accessory pathway and normal His-Purkinje system. The results of atrial mapping during sustained orthodromic SVT revealed a single right paraseptal pathway. After dissection of the posterior septal space, preexcitation was no longer present and orthodromic SVT could no longer be induced. Retrograde atrial mapping during intermittent conduction over a concealed accessory pathway from another patient is illustrated in Figure 4. This patient manifested incessant SVT owing to a concealed posterior septal accessory pathway. During surgery, however, only frequent AV echo beats occurred and sustained SVT could not be induced. Analysis of P-wave morphology using multiple electrocardiographic leads was identical to that observed preoperatively during SVT. Mapping of a single AV echo beat confirmed a posteroseptal concealed accessory pathway. Dissection of the posteroseptal space eliminated SVT postoperatively. Multiple accessory pathways may be suspected preoperatively, but require extensive and laborious intraoperative mapping using conventional procedures. The results of simultaneous mapping from multiple ventricular sites during ventricular preexcitation in a patient suspected of having 2 distinct accessory pathways during the preoperative electro-

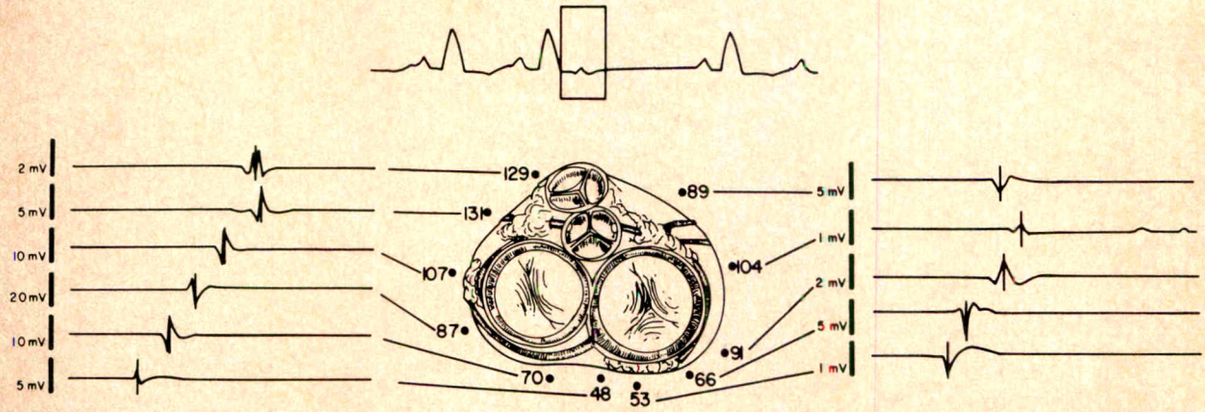

FIGURE 4. Retrograde atrial epicardial activation times during a single atrioventricular echo beat. The accessory pathway was located in the posterior septum.

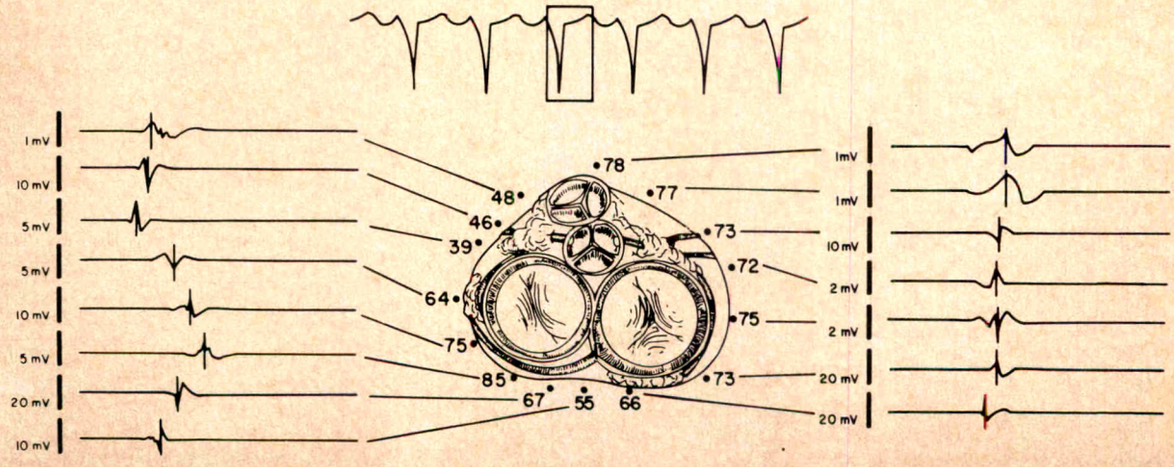

FIGURE 5. Anterograde ventricular epicardial activation showing 2 distinct accessory pathways (left anterolateral and posteroseptal).

physiology study are shown in Figure 5. Analysis of ventricular activation times revealed 2 distinct early sites of activation occurring 39 and 55 ms after the onset of the time window corresponding to a left anterolateral and a posteroseptal location, respectively. Activation of the right ventricle results from impulse propagation clockwise and counterclockwise from these 2 sites and accounts for the poor progression of activation times along the right AV groove. Thus, rapid identification of these 2 accessory pathways was facilitated by simultaneously recording from multiple sites.

Transmural ventricular activation during ventricular preexcitation is illustrated in Figure 6, from a patient in whom a left paraseptal pathway had been localized by the band mapping technique. Two plunge needles located near the left paraseptal tract (electrodes C and D) showed earliest activation at a subepicardial location with reversal of the normal endocardial to epicardial activation patterns. However, the 2 plunge electrodes located at adjacent sites (electrodes A and B) show normal endocardial to epicardial activation. This phenomenon, observed in each of the 3 patients studied in which transmural recordings were obtained, verified the epicardial location of the left free wall Kent bundles.

Discussion

The present report is a summary of our experience using simultaneous epicardial and transmural mapping of the AV groove for rapid and accurate localization of accessory pathways. Simultaneous epicardial mapping of the AV groove affords several distinct advantages over conventional single-probe analysis. First, the band technique offers accurate and rapid identification of accessory pathways and obviates the need for cardiopulmonary bypass during cardiac mapping. Both the ventricular and atrial insertion sites can be identified rapidly using anterograde and retrograde maps. Second, this approach promotes stable pathway conduction by reducing the need for extensive cardiac manipulation during mapping. Third, accurate mapping can be completed during intermittent conduction over the accessory pathway. Fourth, in cases of multiple accessory pathways, distinct pathways can be discerned from a single beat (Fig. 5) or when multiple pacing sites are required to elicit conduction over alternate pathways, several maps can be obtained rapidly.

Previous reports have detailed computer-assisted mapping techniques used to facilitate intraoperative localization of accessory pathways.[6] Techniques for simultaneous multisite mapping have also been reported, including sock arrays[11] and a 4-probe glove.[12] However, the clinical value of these methods has not been documented thoroughly. Band mapping of the AV groove provides a complete assessment of the areas of concern without the need for cumbersome electrode arrays and time-consuming electrode localization procedures. Furthermore, the resolution afforded by the technique is readily expandable because as many as 240 sites can be assessed simultaneously using our current system configuration.

The band mapping technique has no associated morbidity other than that associated with the operation itself. Two potential drawbacks to selective mapping of the AV groove have been discussed previously.[6] First, the presence of abundant epicardial fat in this location can obscure definitive electrical recordings. In this case, the band can be easily repositioned inferiorly to lie further below the AV groove. The other potential problem associated with selective mapping of the AV groove is the unusual occurrence of Mahaim or nodoventricular fibers causing preexcitation. These fibers characteristically have ventricular insertions well below the AV groove. When Mahaim fibers are suspected

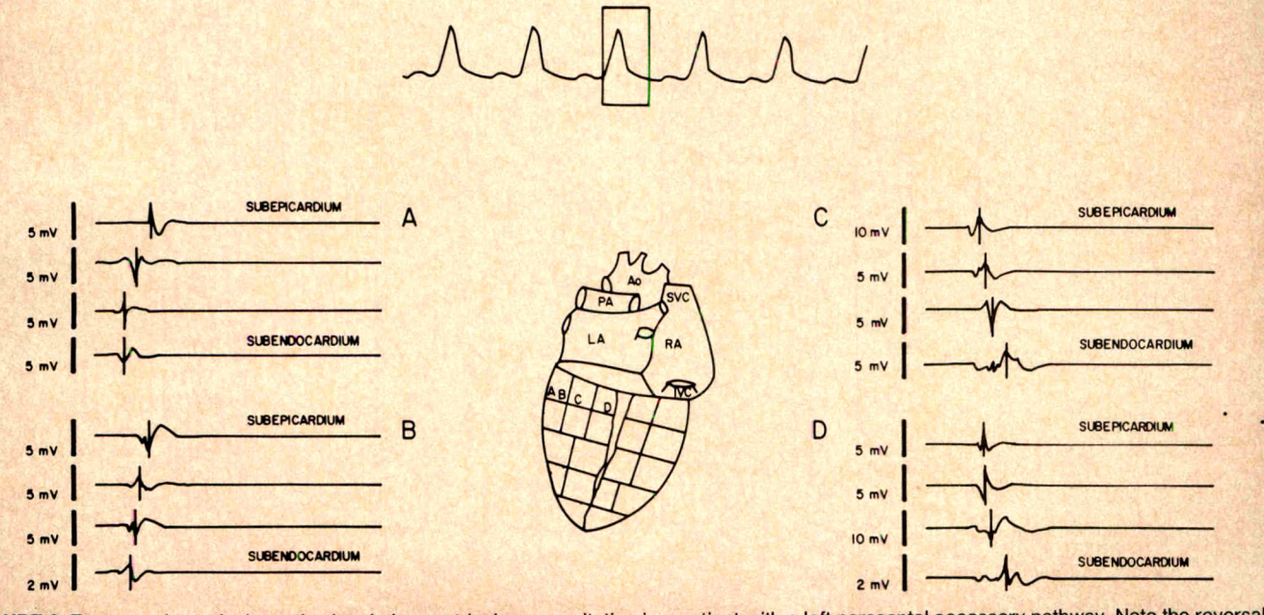

FIGURE 6. Transmural ventricular activation during ventricular preexcitation in a patient with a left paraseptal accessory pathway. Note the reversal of the normal endocardial to epicardial activation pattern recorded from electrodes C and D positioned at the site of ventricular insertion. Normal (endocardial to epicardial) transmural activation is apparent from recordings at electrodes A and B, positioned at adjacent ventricular sites.

preoperatively, more extensive simultaneous intraoperative mapping using an epicardial sock array are required. In addition, the persistence of preexcitation immediately after an ablative procedure would be an indication for complete epicardial mapping.

Analysis of anterograde ventricular and retrograde atrial activation patterns help to guide the surgical division of accessory pathways only if mapping is performed during arrhythmias representative of those occurring clinically, a necessity for conventional or computer mapping systems. During surgery, multiple surface electrocardiographic leads and electrograms from atrial and ventricular reference plaque electrodes are monitored continuously to confirm that electrophysiologic derangements observed intraoperatively are identical to those detected clinically. In this study, ventricular and atrial activation patterns were assessed during a single depolarization of the heart. The ventricles were mapped whenever possible during stable preexcitation and the atria mapped during stable orthodromic SVT. Although complete activation data around the AV groove were available from a single beat, a subsequent beat was routinely analyzed to assure reproducibility of the activation patterns. In 2 patients, intermittent conduction through the accessory pathway occurred intraoperatively (Fig. 3 and 4). In such instances, careful scrutiny of the QRS complex and P-wave morphologies using multiple electrocardiographic leads and comparison to preoperative findings was mandatory before concluding that these isolated beats reflected conduction through the accessory pathway and not spontaneous or mechanically induced ectopic depolarizations. In both patients, conduction through the accessory pathway, although intermittent, occurred on several occasions. In each patient, at least 2 isolated beats were analyzed before decisions regarding the surgical approach were made.

The finding of a reversal in the normal ventricular endocardial to epicardial activation pattern in instances of left free wall pathways supports the concept that these tracts insert epicardially and pass over, rather than under or through, the anular fibrosis.[13] The results of transmural mapping in these patients may have important clinical implications for improved surgical techniques. This finding, however, may not be applicable in right-sided accessory pathways because the anulus of the right ventricle is often deficient on pathologic examination.[13,14]

In conclusion, the technique of simultaneous epicardial mapping of the AV groove provides a rapid and useful means of localizing accessory pathways in patients with the WPW syndrome. Multiple-site mapping of this type may also be useful in facilitating the surgical approach to other arrhythmias, including ventricular tachycardia.

Prospective Comparison of Holter Monitoring and Electrophysiologic Study in Patients with Coronary Artery Disease and Sustained Ventricular Tachyarrhythmias

CHARLES D. SWERDLOW, MD, and JAN PETERSON, RN

Baseline 24-hour Holter monitoring (HM) and electrophysiologic study (EPS) were compared in 43 consecutive patients with coronary artery disease who had sustained ventricular tachyarrhythmias to determine the fraction of patients in whom each could be performed and the fraction in whom each could be used to guide therapy. Patients were excluded from HM if sustained ventricular tachycardia (VT) requiring termination occurred and from EPS if heart failure was sufficiently severe to cause excessive risk. More patients completed EPS than HM (90% vs 71%), but this difference was not statistically significant ($p = 0.12$). Overall, HM detected arrhythmias suitable for antiarrhythmic drug assessment in 50% of patients: 30 or more ventricular premature complexes (VPCs) per hour in 50%, 10 or more VPC pairs in 44%, 5 or more runs in 19%, and 10 or more pairs and runs in 44%. Sustained monomorphic VT suitable for electropharmacologic testing was induced at EPS in 82% ($p = 0.003$ vs HM). Drug efficacy could be assessed in 70% of patients evaluated by HM, compared with 96% evaluated by EPS ($p = 0.02$). Thus, in consecutive coronary patients with sustained ventricular tachyarrhythmias, EPS could be used to guide therapy more frequently than HM.

(Am J Cardiol 1985;56:577–580)

Both electrophysiologic study (EPS) and Holter monitoring (HM) have been used to guide antiarrhythmic therapy in patients with ventricular tachyarrhythmias. The clinical value of either method depends on many factors. Previous investigators have reported the incidence of arrhythmia detection in patients referred for evaluation,[1–9] predictive value of failure to identify an arrhythmia,[4–6] probability of predicting therapy effective,[4,5,7,8] accuracy of therapy prediction,[4,5,7,10] risks[11] and cost.[12] No study has directly compared these 2 approaches to determine fraction of patients in which either could be performed or could be used to guide therapy. We performed both baseline HM and EPS in consecutive patients to address these issues.

Methods

Patients: We prospectively evaluated 33 consecutive patients with coronary artery disease admitted to a community hospital who had spontaneous ventricular fibrillation or sustained ventricular tachycardia (VT) at least 2 months after acute myocardial infarction. Myocardial infarction was diagnosed by characteristic evolutionary electrocardiographic (ECG) and enzymatic changes or pathologic Q waves in 2 or more ECG leads. All patients had at least 90% angiographic narrowing of 1 or more major coronary arteries. We excluded 1 patient who had ventricular fibrillation associated with acute aortocoronary bypass graft occlusion. Characteristics of the remaining 32 patients, all men, are summarized in Table I. Eighteen patients were admitted from the emergency ward, 12 were transferred from intensive care units within 2 days of admission and 2 were transferred from ward beds; only 2 were referred specifically for EPS.

Patients had baseline 24-hour HM after all antiarrhythmic drugs except digoxin were discontinued for 5 half-lives. EPS was performed within 24 hours of completion of HM. Patients were judged ineligible for HM to avoid multiple cardioversions if sustained, symptomatic VT requiring termination occurred during drug withdrawal or HM. In these patients, intravenous lidocaine was administered and withdrawn 8 hours before EPS. If frequent, sustained VT occurred in the baseline state and after antiarrhythmic drug administration, EPS was performed without withholding drugs for 5 half-lives. Patients were judged ineligible for EPS if they had heart failure sufficiently severe to cause excessive risk, defined as New York Heart Association functional class IV and need for continuous vasopressor support.

Holter monitoring: HM was performed with a commercial recorder (ICR 7200) using modified leads V_1 and V_5. Re-

From the Cardiac Arrhythmia Service, Deaconess Medical Center, Spokane, Washington. Manuscript received January 18, 1985; revised manuscript received April 15, 1985, accepted April 22, 1985.

cordings were analyzed using a semiautomated commercial scanner (ICR 6201D). In patients who had bundle branch block or permanent pacemakers, the entire 24-hour recording was printed using a full disclosure system (ICR Variprinter) and hand counted. In the remaining patients, a QRS complex was identified as a ventricular premature complex (VPC) by a template matching system. The accuracy of the template system was verified by the scanner hourly or more often. All VPC pairs and runs of VT were hand validated. VT was defined as 3 or more consecutive ventricular complexes at a mean rate of 100 beats/min or higher. In 3 complex runs of VT, both RR intervals were required to be shorter than 600 ms. Patients were judged eligible for antiarrhythmic drug assessment if the mean VPC frequency was 30 or more per hour or the sum of VPC pairs and VT runs in 24 hours was 10 or more.

Electrophysiologic study: Quadripolar electrode catheters were inserted percutaneously and positioned in the high right atrium, right ventricular apex and His bundle recording position. An electrode catheter was positioned in the left ventricle whenever VT could not be initiated by programmed stimulation from the right ventricle. Three or 4 surface ECG leads were recorded simultaneously with intracardiac electrograms. Stimuli were 2-ms rectangular pulses delivered at 4 times diastolic capture threshold using a Bloom Associates DTU-101 stimulator and stimulus isolator. The threshold was less than 0.5 mA in all patients.

We followed a strict programmed stimulation protocol until either sustained VT was initiated or the protocol was completed. The protocol included: (1) atrial pacing up to the rate at which atrioventricular nodal Wenckebach block occurred, (2) a single extrastimulus delivered from the right ventricular apex in sinus rhythm, (3) up to 3 right ventricular apical extrastimuli in ventricular paced rhythm at 4 basic pacing cycle lengths (600, 500, 430 and 400 ms), and (4) bursts of rapid ventricular pacing to a minimum cycle length of 250 ms. If these techniques failed to initiate sustained VT, the protocol was repeated from the right ventricular outflow tract and at least 2 left ventricular sites. Patients were judged to have no inducible VT if fewer than 5 repetitive ventricular responses were initiated. Induced unsustained VT was defined as VT lasting 6 complexes to 30 seconds. Induced VT was considered monomorphic if QRS morphology was uniform and polymorphic if QRS morphology varied continuously. We considered patients eligible for antiarrhythmic drug assessment only if sustained monomorphic VT lasting longer than 30 seconds was induced.

Statistical analysis: Continuous data are presented as mean ± standard deviation. Basic comparative statistics were calculated using the chi-square test with Yates' correction or Fisher's exact test.

Results

Patient eligibility: Twenty-three patients (71%) completed HM; 9 (29%) did not complete HM, because they had sustained, symptomatic VT that required therapy during drug withdrawal (8 patients) or HM (1 patient). Symptoms of VT were syncope in 8 patients and angina associated with presyncope in 1 patient. VT was terminated by cardioversion in 8 patients and precordial thump in 1 patient. We withdrew antiarrhythmic drug treatment a second time and repeated HM in only 3 of 9 patients in whom HM could not be performed initially. All 3 completed 24 hours of control HM 1 to 3 weeks later, although 2 of them had more than 10 episodes of VT requiring cardioversion or pace termination before and after antiarrhythmic drug administration during the initial period.

TABLE I Patient Characteristics

Characteristics		
No. of pts	32	
Age (yr)	65 ± 11	
Myocardial infarction	32

Monomorphic VT	22	(69%)
Monomorphic VT and VF	7	(22%)
VF	3	(9%)
Cardioversion required	31	(97%)
Cardiac arrest	22	(69%)
Left ventricular function		
Left ventricular end-diastolic pressure (mm Hg)	16 ± 8	(n = 29)
Cardiac index (liters/min/m^2)	2.7 ± 0.7	(n = 29)
Left ventricular ejection fraction*	0.34 ± 0.13	(n = 32)
NYHA functional class		
I	0	(0%)
II	15	(47%)
III	12	(37%)
IV	5	(16%)

* Left ventricular ejection fraction was determined by contrast ventriculography in the 30° right anterior oblique projection in 29 patients and by radionuclide ventriculography in 3 patients.
NYHA = New York Heart Association; VF = ventricular fibrillation; VT = ventricular tachycardia.

One eligible patient did not undergo EPS at the request of his referring physician; EPS was performed in 28 of the remaining 31 patients (90%). Three patients were considered ineligible for EPS because of severity of heart failure (left ventricular ejection fraction 0.14 ± 0.03, pulmonary capillary wedge pressure 25 ± 6 mm Hg, and cardiac index 1.9 ± 0.2 liters/min/m^2). At the time of EPS, antiarrhythmic drugs had been withheld for 5 half-lives (23 patients) or were present in subtherapeutic concentrations (lidocaine less than 0.3 μg/ml, 3 patients) in 26 of 28 patients (93%). Clinically significant antiarrhythmic drug plasma concentrations (lidocaine 2.6 μg/ml, procainamide 3.4 μg/ml) were measured in 2 patients at the time of EPS; both had more than 10 episodes of spontaneous, monomorphic, sustained VT in the baseline state and after drug administration. No patient had complications as a result of EPS.

Although EPS could be performed in more patients than HM, this difference was not statistically significant ($p = 0.12$). EPS was completed more frequently than HM in patients admitted through the emergency ward (15 of 17 [87%] vs 11 of 18 [61%], $p = 0.14$), but not in patients transferred from other hospitals (13 of 14 [93%] vs 12 of 14 [86%], difference not significant).

Arrhythmia detection: The prevalence of arrhythmias recorded by HM is shown in Table II. Drug assessment could be performed in 16 patients (50% of all patients, 70% of patients completing HM). Thirteen of the 18 patients (72%) in whom VT was recorded during HM had 6 or fewer episodes: 1 episode in 7 patients, 2 episodes in 2 patients, 3 episodes in 2 patients, and 4, 6, 20, 22, 34, 98 and 6,626 episodes in 1 patient each. The longest episodes were 3 complexes in 7 patients, 4 to 6 complexes in 6 patients, 7 to 10 complexes in 4 patients and 5 minutes in 1 patient. In the 16 patients with the fewest episodes, most episodes were short: 74% were 3 complexes in duration, 21% were 4 or 5 complexes, and 5% were 6 to 8 complexes. The patient who had 98 episodes had 88 episodes longer than

TABLE II Prevalence of Arrhythmias in 23 Patients Who Completed Holter Monitoring

Arrhythmia Type	Arrhythmia Frequency						
	0–1	2–9	10–29	30–99	100–299	300–999	≥1000
VPCs/hour	2	2	3	6	5	3	2
		0	1–5	6–9	10–29	30–99	≥100
VPC pairs/24 hours		3	6	2	2	1	9
VT runs/24 hours		7	10	1	2	2	1
Pairs + runs/24 hours		2	5	4	2	1	9

VPC = premature ventricular complex; VT = ventricular tachycardia.

10 complexes, the longest lasting 5 minutes; the longest episode in the patient who had 6,626 runs was 10 complexes.

Sustained monomorphic VT suitable for drug assessment was induced in 27 patients at EPS (87% of patients, 96% of eligible patients). A maximum of 13 complexes of polymorphic VT was induced in 1 patient, whose clinical arrhythmia was ventricular fibrillation. Sustained VT morphologically identical to the clinical arrhythmia was induced in both patients in whom initial EPS was performed in the presence of significant antiarrhythmic drug concentrations.

Overall, arrhythmias suitable for antiarrhythmic drug evaluation were detected more frequently by EPS than by HM: 87% vs 50% ($p = 0.003$) for all patients and 96% vs 70% ($p = 0.02$) for patients completing EPS or HM.

Discussion

Both HM and EPS have been used to guide long-term antiarrhythmic therapy in patients who have sustained ventricular tachyarrhythmias. This study prospectively determined the fraction of consecutive patients with coronary artery disease in whom each technique could be performed and used to select therapy.

HM was completed in 71% of patients and antiarrhythmic therapy was assessed in 50% (70% of evaluated patients). Ezri et al[7] recorded baseline HM in 19 patients with ventricular tachyarrhythmia, with similar results: 63% had 30 or more VPCs/hour, 58% had VPC pairs and 21% had VT.

In contrast, Graboys et al[8] reported that 100 of 106 patients (94%) with ventricular tachyarrhythmia completed baseline 48-hour HM. VPC pairs were detected in all 100 patients and VT in 90; VPC frequency was not reported. The difference in applicability of HM between our study and theirs may be a result of our higher incidence of emergency admissions (56% vs 0%); 86% of our patients who were not emergency admissions completed HM. The causes of disparity in the prevalence of recorded arrhythmias are less certain; differences in duration of monitoring[13] and patient populations may be factors.

Previous detailed analyses of HM ventricular arrhythmia complexity have been limited to ambulatory populations of apparently healthy persons,[14,15] patients with coronary disease,[16,17] and postinfarction patients.[13,17,18] As expected, the frequency and complexity of recorded arrhythmias were greater in our patients than in those populations, but the characteristics of recorded VT were similar: In ambulatory populations, 50 to 74% of 24-hour recordings that show VT had only a single episode,[19,21] 30 to 47% had only 3 complex runs,[19,20] and 16 to 55% of episodes were 3 complexes in duration.[21–23] We found that 39% had only a single episode, 39% had only 3 complex runs, and 74% of episodes in the 16 patients with fewest episodes were 3 complexes in duration.

In our study, EPS could be used to assess drug therapy more frequently than HM. Although 56% of our patients were admitted through the emergency ward and only 16% were referred specifically for EPS, the incidence and types of induced arrhythmias in our patients are similar to those reported for patients referred for EPS who had sustained VT,[1–3] ventricular fibrillation[4] or cardiac arrest.[4,5]

No programmed stimulation protocol is completely sensitive and specific. Protocols such as ours that use 3 extrastimuli have been reported to initiate clinical VT in 12 to 24% more patients than protocols using only 2 extrastimuli[2,3] as well as nonclinical polymorphic VT in up to 31% of patients without spontaneous VT.[3] To avoid false-positive outcomes, we considered only induced, sustained monomorphic VT suitable for drug assessment. Induced, polymorphic VT, which may be clinically relevant in some patients[5] and not in others,[2,3] was judged a finding of uncertain significance.

Patients who have frequent sustained VT present a particularly difficult management problem. Although suppression of spontaneous sustained arrhythmias has been used to measure drug efficacy in these patients, this approach did not distinguish spontaneous variability in arrhythmia frequency from drug effect in the 3 patients in whom we repeated baseline HM after it could not be performed initially. In contrast, EPS may be used to evaluate therapy without discontinuing antiarrhythmic drugs if the clinical arrhythmia is induced.

Our study has several limitations. We compared HM and EPS only for the fraction of patients in whom either could be used to guide therapy; we did not analyze the likelihood of predicting therapy effective, accuracy of therapy prediction, time required for therapy identification, costs, risks or institutional availability. Our population had a high proportion of acutely ill patients, and our results may not apply to a population of electively referred patients. Because HM and EPS measure different arrhythmias and the minimum arrhythmia suitable for therapy evaluation by either method is

uncertain, any comparison of these methods for arrhythmia detection must apply arbitary criteria. Our incidence of detection of arrhythmias by HM would have been lower if we had analyzed only repetitive forms. It might have been higher if we had used a longer monitoring duration[13] or continued monitoring after patients required cardioversion, although the latter approach would have limited practical, clinical application. Our incidence of induced arrhythmias suitable for EPS drug assessment might have been slightly higher if we had included polymorphic VT, but our results would have been less specific.

Both HM and EPS have specific advantages and limitations; they are neither universally applicable nor mutually exclusive. In selecting a method to evaluate antiarrhythmic therapy, our findings should be considered in conjunction with other relevant data.

Comparative Efficacy and Safety of Oral Tocainide and Quinidine for Benign and Potentially Lethal Ventricular Arrhythmias

JOEL MORGANROTH, MD, CARL OSHRAIN, MD, and PETER P. STEELE, MD

The antiarrhythmic efficacy and safety of oral tocainide hydrochloride and quinidine sulfate were compared in a double-blind, 3-center, parallel trial involving 133 patients with benign and potentially lethal ventricular arrhythmias. Baseline demographic, etiologic, functional and ventricular arrhythmia data were not significantly different between the 2 groups. Two weeks of an initial placebo period were followed by 8 weeks of active drug treatment, concluding with 4 weeks of washout. Frequent 24-hour ambulatory electrocardiographic monitoring was used to judge efficacy. Ten of 27 patients (37%) receiving tocainide and 12 of 24 patients (50%) receiving quinidine had a 75% reduction with drug treatment compared with the initial placebo period ($p > 0.25$). Total abolition of ventricular tachycardia occurred in 6 of 16 patients (37%) receiving tocainide and 6 of 13 patients (43%) receiving quinidine ($p > 0.25$). Conditions that required discontinuation of therapy occurred in 18 of 67 patients (27%) receiving tocainide and 16 of 66 (24%) receiving quinidine (difference not significant). More patients had dizziness during tocainide treatment and diarrhea during quinidine treatment. Quinidine caused a prolongation in the QT interval (0.03 second); tocainide caused a slight reduction (0.01 second). No important changes in vital signs or laboratory measurements were observed in left ventricular ejection fraction when measured. Thus, tocainide, the new oral analog of lidocaine, appears to be as safe as quinidine but is slightly less effective in suppressing ventricular arrhythmias.

(Am J Cardiol 1985;56:581–585)

Ventricular arrhythmias are important in predicting sudden cardiac death.[1] In more than 80% of patients wearing a Holter monitor sudden death was the result of a ventricular tachyarrhythmia that led to ventricular fibrillation.[2] Ventricular arrhythmias occur in 3 clinical settings, which are defined by their immediate hemodynamic consequence and their potential risk of causing sudden cardiac death[3]: benign, potentially lethal and lethal. Whether sudden cardiac death can be prevented by antiarrhythmic therapy is still an unsettled question and can be answered only by properly constituted trials.[4,5] Nevertheless, antiarrhythmic treatment for ventricular arrhythmias that are symptomatic, that cause hemodynamic sequelae or that are lethal is part of the daily practice of clinicians.

Tocainide is a new antiarrhythmic agent with effects similar to those of lidocaine; thus, it is considered a class IB agent.[6] Tocainide increases ventricular fibrillation threshold in ischemic and nonischemic models.[7] It has little effect on electrocardiographic (ECG) intervals or myocardial hemodynamic status and its 15-hour half-life permits 2- or 3-times-daily dosing schedules. Placebo-controlled studies have shown that tocainide is effective[8] in about 50% of patients with benign and potentially lethal ventricular arrhythmias.[6] This report details the results of a multicenter clinical trial aimed at comparing the efficacy and safety of oral tocainide with those of the standard class IA antiarrhythmic agent, quinidine, in patients with benign and potentially lethal ventricular arrhythmias.[3]

Methods

Trial design: This was a 14-week, parallel, randomized, double-blind, quinidine-controlled, 3-center (Philadelphia, Rochester and Denver), outpatient study. Patients included in this trial were adults (older than 18 years) with benign or potentially lethal ventricular arrhythmias. The principal inclusion criterion was the presence of frequent ventricular premature complexes (VPCs), averaging at least 60 per hour over 48 hours of ambulatory monitoring during 2 weeks of

placebo therapy. All antiarrhythmic drugs, including β blockers (but excluding digitalis preparations), were discontinued before the initial 2-week placebo period. Patient exclusion criteria included known allergy to quinidine or amide-type local anesthetic agents, myasthenia gravis, use of a cardiac pacemaker, a creatinine level above 2.5 mg/dl, the presence of second- or third-degree atrioventricular (AV) block, trifascicular block, right bundle branch block with left posterior hemiblock, a prolonged QT interval syndrome or Wolff-Parkinson-White syndrome.

After signing the informed consent form, which had been approved by the local Institutional Review Boards, the patients began a 2-week baseline period during which 2 placebo tablets were taken orally every 6 hours. Eligible patients were assigned to 1 of 2 treatment groups according to an allocation schedule of random numbers. Patients received either 600 mg of tocainide hydrochloride every 12 hours or 300 mg of quinidine sulfate every 6 hours for the 8 weeks of active treatment. Participants were required to take 2 kinds of tablets (tocainide or its placebo and quinidine or its placebo) to maintain the double-blind design of the trial. Then, patients entered a 4 week post–active drug treatment period, when placebo was again administered as 2 tablets every 6 hours. During the initial placebo period each patient underwent a complete medical history, weekly physical examination, a 12-lead electrocardiogram, ophthalmologic examination, chest radiograph and complete clinical laboratory screening. Patients were also evaluated at weeks 3, 4, 6, 8 and 10 during the active drug period and as well as weeks 12 and 14 during the final

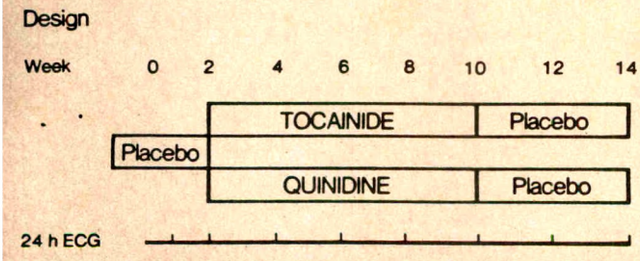

FIGURE 1. The placebo-controlled, parallel study design using tocainide, 600 mg twice daily, and quinidine, 300 mg 4 times daily. Twenty-four-hour Holter recordings (ECG) were recorded as shown.

placebo. On each of these 9 occasions, vital signs were recorded, a history was taken and physical examination was performed. Ophthalmalogic and chest radiographic examinations were repeated during the placebo period after treatment. Clinical laboratory screening was obtained during weeks 1, 4, 10 and 12 and a 24-hour continuous Holter monitoring recording was performed during weeks 1, 2, 4, 6, 8, 10, 12 and 14 (Fig. 1).

In the Denver center, 13 patients were subjected to a noninvasive determination of left ventricular ejection fraction using a dynamic gated radionuclide angiographic technique. This test was performed during the placebo periods before and after treatment and at the end of 6 weeks of active drug therapy.

Data analysis: For the cardiovascular and quantitative laboratory parameters, within-group test of changes from before treatment were performed by combining the Wilcoxon signed rank statistics for each investigator. To assess interaction between investigator and treatment and of investigator main effects, an analysis of variance on the overall relative ranks was performed. Between group tests of treatment effects were performed using a nonparametric (rank) randomized block analysis on ranks within each block (investigator). When there was a significant between-group difference before treatment and it appeared that the difference might affect the analysis of changes from before treatment, an analysis of covariance was performed on the actual values using the baseline value as the covariate. Qualitative laboratory parameters and adverse effects were analyzed using Fisher's exact test on 2 × 2 tables. The significance level for the test of interaction was 0.10; all other tests used the 0.05 significance level.

The efficacy of tocainide and quinidine was evaluted by comparing the VPC frequency on the available 24-hour Holter recordings during the active drug period with the average of the two 24-hour Holter recordings during the initial 2-week placebo period. A 75% reduction in VPC frequency was considered to be an effective response. The number of responders per treatment group was compared using Fisher's exact test on 2 × 2 tables.

A central research facility (the Cardio Data Systems of United Medical Corp., Haddonfield, New Jersey) was used to analyze all of the 24-hour recordings from the 3 centers. Analysts were blinded as to the treatment of the patient. Details of the nature of the system as well as its quality control features, validity, reproducibility and precision have been reported.[9]

Results

Patient characteristics: The 3 centers enrolled a total of 136 patients. Three of these 136 patients never received active drug treatment, 26 were discontinued from the study because of inadequate VPC frequency during the pretreatment baseline period, 34 were discontinued before completing the trial because of adverse reactions (1 during the final placebo period) and 2 were discontinued for administrative reasons. Table I is a list of the baseline characteristics for the 67 patients who randomized to tocainide and to the 66 patients randomized to quinidine. There were no significant differences between the 2 drug groups for any of the categories listed.

Suppression of ventricular arrhythmias: When patients are considered who met the inclusion baseline VPC frequency (at least 60 per hour) criteria and when patients who were withdrawn because of adverse reactions or administrative reasons are considered as

TABLE II Degrees of Suppression of Ventricular Premature Complexes in the Two Drug Groups

		VPC Suppression (%)				
	n	<49	50–74	75–84	85–99	100
Tocainide	27	13	4	4	4	2
Quinidine	24	7	5	1	9	2

VPC = ventricular premature complex.

treatment failures, then 101 patients are analyzable for the determination of suppression of ventricular arrhythmias. A 75% reduction on active drug treatment compared to the pretreatment placebo period was found in 12 of 54 patients (22%) randomized to tocainide and 18 of 47 (38%) randomized to quinidine ($p = 0.086$). Figure 2 details the mean suppression of VPCs during the 3 phases of the protocol in patients randomized to quinidine or tocainide. For patients with ventricular tachycardia in the pretreatment period, complete abolition of ventricular tachycardia was seen in 8 of 38 patients (21%) randomized to tocainide and 10 of 28 (36%) randomized to quinidine ($p > 0.25$).

When patients with inadequate VPCs at baseline patients who discontinued for administrative or adverse reactions and, those who did not have a return of VPCs on the Holter monitor obtained in the final placebo period are excluded, then 51 patients are available for efficacy analysis. A 75% reduction in VPCs was observed in 10 of 27 patients (37%) randomized to tocainide and 12 of 24 (50%) randomized to quinidine ($p > 0.25$). Complete abolition of ventricular tachycardia occurred in 6 of 16 patients (37%) randomized to tocainide and 6 of 13 (43%) randomized to quinidine ($p > 0.25$). Table II is a list of the percent reduction using several different categories in comparing patients treated with tocainide or quinidine for VPCs.

Adverse reactions: Thirty-four of 67 patients (51%) receiving tocainide and 42 of 66 (64%) receiving quinidine reported adverse effects (difference not significant [NS]). Reactions requiring discontinuation from the protocol occurred in 18 of 67 patients (27%) receiving tocainide and 16 of 66 (24%) receiving quinidine (NS). Table III is a list of reasons for withdrawal in the 2 treatment groups. There were significant differences between the treatment groups in the prevalence of dizziness and diarrhea (Fig. 3).

TABLE III Adverse Reactions

Reason for Withdrawal	Tocainide (n = 67)	Quinidine (n = 66)
CNS (ataxia, tremor, dizzy)	8	0
Rash	4	5
CNS and gastrointestinal	3	4
Gastrointestinal (diarrhea, nausea, vomiting and anorexia)	1	3
Congestive heart failure	1	1
Death	1	1
Intercurrent viral infection	0	1
Atrial fibrillation and VT	0	1*
Total	18 (27%)	16 (24%)

* Occurred in post drug placebo period.
CNS = central nervous system; VT = ventricular tachycardia.

Proarrhythmia electrocardiogram and other laboratory parameters: Two patients died, one in each group, on the 21st day of therapy. Neither death was considered to be related to the active drug by the treating investigator. In this trial, no patient had greater than a 3-fold increase in VPC frequency during active therapy compared with control and no patient had sustained ventricular tachycardia during active drug treatment.

PR and QRS intervals did not change significantly during active drug treatment compared to baseline in either the tocainide or quinidine group. There was a significant increase in the QT interval during therapy with quinidine (a mean increase of 0.03 second) com-

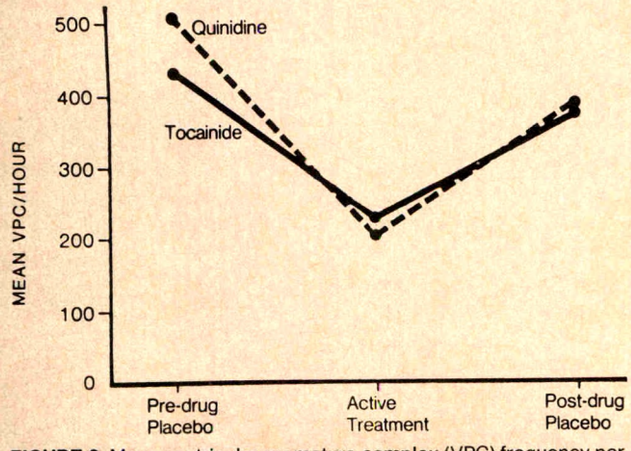

FIGURE 2. Mean ventricular premature complex (VPC) frequency per hour from Holter monitoring data for patients randomized to quinidine and tocainide. Predrug placebo, active treatment and the postdrug placebo periods are compared.

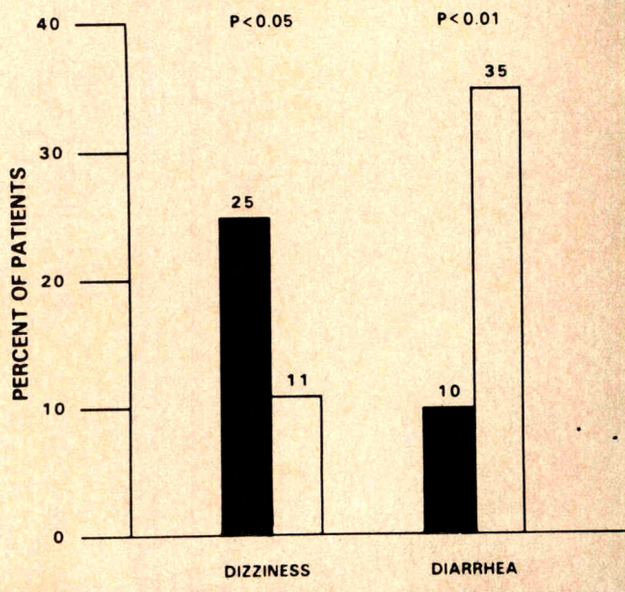

FIGURE 3. The percent of patients experiencing the adverse reactions of either dizziness or diarrhea with tocainide (**solid bars**) and quinidine (**open bars**) treatment (n = 133).

pared with the QT interval in patients receiving tocainide, which either did not change or decreased 0.01 second at week 6 on therapy ($p < 0.01$).

No clinically significant changes occurred in vital signs or laboratory tests nor were there any significant changes on comparing the chest radiographic and ophthalmologic evaluations before and after treatment.

Left ventricular function: In the Denver center, 13 patients (7 receiving tocainide and 6 receiving quinidine) were studied by radionuclide angiography. After 6 weeks of treatment the mean left ventricular ejection fraction decreased slightly, by 26% from the initial placebo baseline mean of 35.6% ($p < 0.05$). The mean ejection fraction returned toward the initial baseline value after the 4-week posttreatment placebo period, but remained lower than baseline (mean 34.0%). No significant difference was detected between the 2 placebo periods. The mean left ventricular ejection fraction in the quinidine-treated group decreased slightly, by 0.12%, from an initial baseline mean of 38.5%. At the end of the posttreatment placebo treatment the ejection fraction decreased further, to a mean of 36.0%, which was significantly lower than that during the initial baseline period ($p < 0.01$). No significant differences were detected between treatment groups during the placebo and active drug periods. There was no significant reduction in clinical hemodynamic stability in any of the patients evaluated.

Discussion

This double-blind, parallel, 3-center study compared the efficacy and safety of oral tocainide, 600 mg every 12 hours, with quinidine sulfate, 300 mg every 6 hours, in patients with benign and potentially lethal ventricular arrhythmias. The results indicate that these 2 agents *at the doses used* are comparable in terms of safety, although quinidine is slightly more effective than tocainide.

Quinidine was chosen as the comparison agent because it is one of the most commonly used antiarrhythmic agents available in the United States and frequently serves as a standard comparative agent.[9–12] In this study, 38 to 50% of patients responded at the 75% level of VPC reduction, depending on the criteria used for patient inclusion for analysis. A range of 50 to 75% of patients responding to quinidine therapy has been shown in other studies[9–11] using doses of quinidine sulfate up to 400 mg every 6 hours. Twenty-two to 37% of patients receiving tocainide achieved a 75% VPC reduction. A total of 10 short-term placebo controlled tocainide trials in 99 patients have been performed using tocainide, with doses of 200 to 800 mg every 8 hours to 400 to 1,000 mg every 12 hours. Approximately 51% of patients have shown a more than 75% suppression in VPC frequency.[3] Tocainide has also been shown to be effective in the suppression of ventricular ectopy in postinfarction patients and during long-term treatment.[13,14] Three trials have been reported that compared the effectiveness of tocainide to that of procainamide, with no significant differences being demonstrated in effectiveness or safety. Each of these 3 studies has methodologic limitations.[15–17] A limitation of the efficacy data in this study is that multiple doses of quinidine and tocainide were not compared, thus eliminating the evaluation of a true dose-response comparison of these 2 agents. However, the doses of tocainide and of quinidine were considered to be the usual effective clinical dose in which side effects are mild or minimized.

Approximately one-fourth of the patients receiving both tocainide and quinidine discontinued treatment because of adverse reactions. The most frequent reason for discontinuation in the tocainide group was related to its central nervous system effects in which ataxia, tremor and dizziness were primarily manifested. Conversely, the gastrointestinal side effects predominated in patients receiving quinidine and diarrhea but also nausea, vomiting and anorexia were often seen. These percentages of side effects are quite similar to those reported in other studies.[9,10,16,18]

As could be predicted from the electrophysiologic effects, quinidine caused a prolongation of the QT interval by lengthening the JT segment, whereas tocainide had either no effect or caused a slight reduction. No significant changes were seen in the PR or QRS intervals in this study. No patient had a proarrhythmic response. The lack of QT interval prolongation by tocainide may imply that the potential for induction of a serious ventricular proarrhythmic event may be less common with tocainide than with other classes of antiarrhythmic agents.[19]

No significant changes in vital signs, laboratory variables or important hemodynamic changes were induced by either quinidine or tocainide. No patient had symptoms of congestive heart failure with either drug.

Tocainide to lidocaine are similar in their electrophysiologic and hemodynamic effects. Often, one can predict the response to tocainide by the response to lidocaine.[6] Also important is the fact that tocainide has no important interactions with β blockers, digoxin or coumadin.[6] Thus, this study has also shown that the efficacy and safety of tocainide compare favorably to quinidine, and tocainide is only slightly less effective. Tocainide's advantages of not prolonging the QT interval, of having no important negative inotropic or proarrhythmic effects, and of being useful even with a twice-daily dosage schedule, which promotes compliance suggest, that tocainide will be a useful addition to the antiarrhythmic armamentarium.

Incidence of Proarrhythmic Effects from Quinidine in the Outpatient Treatment of Benign or Potentially Lethal Ventricular Arrhythmias

JOEL MORGANROTH, MD, and LEONARD N. HOROWITZ, MD

To determine the prevalence and importance of proarrhythmic events secondary to the initiation of quinidine therapy in outpatients with benign or potentially lethal ventricular arrhythmias, the data from 360 patients treated with quinidine as part of 3 outpatient drug trials were retrospectively reviewed. These patients had at least 30 ventricular premature complexes per hour during placebo treatment and had no evidence of unstable clinical states, hypokalemia, digitalis toxicity, atrial fibrillation or a prolonged QT interval (longer than 0.50 second). The quinidine dose varied from 200 to 400 mg 4 times a day for 2 to 4 weeks. Proarrhythmic effect was defined on Holter monitoring as a 400% increase in frequency of ventricular premature complexes, the presence of new ventricular tachycardia not previously identified or a 10-fold increase in the number of beats of ventricular tachycardia. There was no difference in the demography, response to quinidine therapy or side effects on quinidine among the 3 trials. Six of 360 patients (2%) had a proarrhythmic response and none of these patients had hemodynamic symptoms, required hospitalization or died from the proarrhythmic event. Thus, quinidine can be safely initiated to outpatients who meet the inclusion criteria cited herein.

(Am J Cardiol 1985;56:585–587)

Although antiarrhythmic drugs have been used for several decades, only recently has their full potential to aggravate or induce ventricular arrhythmias (the so-called proarrhythmic effect) been appreciated.[1,2] However, the prevalence of proarrhythmic events resulting from antiarrhythmic drug treatment is different in patients with benign and potentially lethal ventricular arrhythmias[1,3] from those with lethal ventricular arrhythmias. Benign ventricular arrhythmias are those that occur in patients with no structural heart disease, do not produce hemodynamic consequences, and have a very low risk of associated sudden cardiac death. Lethal ventricular arrhythmias cause immediate hemodynamic consequences (such as syncope and symptomatic hypotension) and are associated with the highest rate of sudden cardiac death. Patients with lethal ventricular arrhythmias usually have markedly depressed left ventricular function and severe structural heart disease. Patients with potentially lethal ventricular arrhythmias have structural heart disease or compromised left ventricular function such that the presence of ventricular arrhythmias is associated with an increased risk of sudden death. These arrhythmias, however, do not cause hemodynamic symptoms and the only indication for their treatment is the hope that their suppression will prevent sudden cardiac death. Antiarrhythmic treatment of patients with lethal ventricular

TABLE I Demographic Characteristics of the Three Trials

	A	B	C
Pts receiving quinidine	139	154	67
Mean age (yr)	58	60	59
Men	69%	71%	69%
CAD	52%	51%	47%
VPCs/24 hours at baseline (Mean ± SD)	429 ± 423	451 ± 466	417 ± 413

CAD = coronary artery disease; SD = standard deviation; VPC = ventricular premature complexes.

arrhythmias is properly initiated in hospital using monitoring facilities and careful drug dosing. Although there is increasing concern regarding proarrhythmic effects, the actual frequency of these events during outpatient initiation of antiarrhythmic therapy is uncertain. Therefore, many physicians have also resorted to hospitalizing patients with benign or potentially lethal arrhythmias before initiating drug therapy to control ventricular arrhythmias. Because of the impact of new prospective reimbursement schedules and the high cost associated with continuous electrocardiographic (ECG) monitoring in hospital, we retrospectively reviewed 3 large antiarrhythmic drug trials to determine the prevalence and importance of proarrhythmic events secondary to the initiation of quinidine in outpatients with benign or potentially lethal ventricular arrhythmias.

Methods

The data from 3 clinical drug trials in which patient entry criteria were identical (patients had to have either benign or potentially lethal ventricular arrhythmias without a history of lethal ventricular arrhythmias) were pooled. All patients had a minimum average of 30 ventricular premature complexes (VPCs) per hour on at least two 24-hour Holter monitors during placebo treatment at least 1 week after discontinuation of all prior antiarrhythmic agents. In all 3 trials patients were excluded if they had evidence of prior allergy or severe side effects to quinidine, or had hypokalemia, digitalis toxicity, atrial fibrillation, or second- or third-degree atrioventricular block. No patient had a myocardial infarction within 6 weeks of entry or uncontrolled noncardiac disease or uncompensated congestive heart failure (New York Heart Association class III or IV). Patients with a QT interval that was longer than 0.50 second were also excluded.

Ambulatory electrocardiographic monitoring in all 3 trials was analyzed by the same independent research analysis service (Cardio Data, Inc., United Medical Corp., Haddonfield, NJ). All patients had at least 1 Holter recording at least 18 hours in duration while receiving quinidine.

One trial was a 16-center, parallel, double-blind, placebo-controlled trial of flecainide acetate vs quinidine sulfate in 342 outpatients.[4] In this trial, 139 patients were placed on quinidine therapy after 1 week of placebo treatment. Two 24-hour Holter recordings established entry criteria. Quinidine was then prescribed initially at a dose of 300 mg 4 times daily for 2 weeks followed by 400 mg 4 times daily if an 80% reduction in VPC frequency was not seen during treatment with the lower dose.

The second trial was a 9-center, crossover, double-blind, placebo-controlled trial of encainide hydrochloride vs quinidine sulfate in 187 patients. One hundred fifty-four patients received quinidine. (Some patients were discontinued after initial randomization to encainide before quinidine therapy.)

TABLE II Efficacy and Safety of Quinidine in the Three Trials

	A	B	C
Pts responding			
VPCs	55%	67%	53%
VT	66%	78%	41%
Side effects			
Any	65%	74%	41%
% D/C	15%	25%	27%

D/C = discontinued from study because of side effects; VPCs = ventricular premature complexes; VT = ventricular tachycardia.

After 1 week of placebo and two 24-hour Holter recordings, patients initially received 200 and then 400 mg of quinidine sulfate 4 times daily each for 1 week. The larger dose was used only if at least a 75% reduction in VPC frequency was not seen on the lower dose.

The third study was a 1-center, parallel, single-blind, controlled trial comparing 4 types of quinidine in 67 patients. After 1 week of washout during placebo therapy and two 24-hour Holter recordings to establish entry criteria, patients were randomized in a parallel fashion to 4 types of quinidine, each for 3 weeks, with three 24-hour Holter recordings obtained during this time. Quinidine sulfate, using either 1,200 mg of Quinora® (Eli Lilly) or the extended preparations Quinidex® (AH Robins) or Quiniday® (AH Robins) were prescribed or quinidine gluconate (Quinaglute Dura Tabs®, Berlex Laboratories) at a dose of 1,296 mg/day.

The definition of proarrhythmic effect (on Holter monitoring) used in this trial was adopted from that of Velebit et al,[5] who required at least a 400% increase in VPC frequency with quinidine treatment compared to baseline; the presence of new ventricular tachycardia (VT) not previously identified or a 10-fold increase in the number of beats of VT during quinidine treatment compared to the baseline.

Results

The demographic information comparing all 3 clinical trials indicate that there were no statistically significant differences in the age, gender, proportion with coronary artery disease, or ventricular arrhythmia frequency at baseline (Table I).

The percent of patients responding with at least 75% reduction in VPC frequency compared with control in these trials as well as a 75% reduction in beats of VT are shown in Table II. Again, there was no statistically significant difference between the 3 trials in the efficacy of quinidine to control VPCs or VT. Table II also details the prevalence of side effects reported during the trial and the percent of patients requiring premature discontinuation during the trial because of an adverse effect to quinidine. Again, no statistically significant differences were seen between the 3 trials.

The proarrhythmic responses in these 3 trials based on the criteria noted above are described in Table III. The prevalence of a proarrhythmic effect observed was 2%; no patient had hemodynamic symptoms, required hospitalization or died from a proarrhythmic event. Three patients in the flecainide-quinidine trial died,[4] but all 3 deaths were documented to be the result of acute myocardial infarction. Four patients in the encainide-quinidine trial had QT intervals longer than 0.55 second during quinidine treatment, but no patient was observed to have this effect in the other 2 trials.

Discussion

The occurrence of a proarrhythmic effect induced by antiarrhythmic therapy is particularly important in patients with benign or potentially lethal ventricular arrhythmias, because reduction of VPCs in these patients has not been determined to result in prevention of sudden death. If antiarrhythmic agents are used in these patients special cautions are necessary to be certain of their safety and efficacy. A follow-up Holter recording is mandatory after initiating antiarrhythmic therapy to be certain that the proarrhythmic effect is absent and that the agent is effective.[1,3]

In this report we evaluated the safety of initiating quinidine to outpatients as antiarrhythmic treatment. The data clearly document that in patients with benign or potentially lethal ventricular arrhythmias in a stable clinical state and without hypokalemia or atrial fibrillation, quinidine therapy is safe to initiate in the outpatient setting, because the rate of a proarrhythmic effect was only 2% and no patient had a serious hemodynamic adverse reaction or sudden death or required hospitalization. Quinidine was chosen as the reference agent because it is the most commonly used antiarrhythmic agent in the United States.[4]

The 3 trials reviewed were comparable even though they were performed at different times. All 3 used the same central laboratories for data analysis, similar dosing schedules and duration of therapy, and they were comparable in demographic and clinical factors between the patient groups. In addition, the efficacy and side effect rates in these trials during quinidine therapy were comparable. Therefore, the ability to examine these 3 study groups as a homogeneous population to define the prevalence of proarrhythmia appears to be valid. The results of these trials and the safety of outpatient initiation of quinidine are relevant to patients only with benign or potentially lethal ventricular arrhythmias and without hypokalemia, digitalis toxicity and atrial fibrillation. Patients with more severe left ventricular dysfunction, especially if associated with these abnormalities, and patients with lethal ventricular arrhythmias were not studied herein, and these patients have had a higher prevalence and severity of proarrhythmic effects than the patients reported in this study.[1] Until the proarrhythmic prevalence and severity are determined in such patients, they should have quinidine initiated in hospital under ECG monitoring.

TABLE III Proarrhythmic Response in the Three Trials

	A (n = 139)	B (n = 154)	C (n = 67)
VPC 400% inc.	2	2	0
New VT	0	0	0
VT 1,000% inc.	0	0	2
QT >0.55	0	4	0
Deaths	3 (All MI)	0	0
Proarrhythmic effect = 6/360 (2%)			

Inc. = increase; MI = myocardial infarction; VPC = ventricular premature complexes; VT = ventricular tachycardia.

Ambulatory Electrocardiographic Recordings at the Time of Fatal Cardiac Arrest

PETER G. MILNER, MB, ChB, EDWARD V. PLATIA, MD, PHILIP R. REID, MD, and LAWRENCE S.C. GRIFFITH, MD

The relation between arrhythmias at cardiac arrest and the outcome of arrest is poorly understood. The Holter monitor tracings of 13 patients were reviewed after they sustained an in-hospital cardiac arrest during ambulatory electrocardiographic monitoring. All had a prior cardiac arrest or cardiac syncope. Twelve patients had ventricular tachycardia (VT) as their initial arrest arrhythmia and 1 patient had bradycardia followed by ventricular fibrillation (VF). VT degenerated to VF in 10 of 12 patients after a mean interval of 96 ± 31 seconds (± standard error of the mean). The number of VT runs increased significantly during the hour immediately preceding arrest ($p = 0.004$). Despite prompt resuscitation efforts in 12 patients, only 6 survived. The 6 survivors and 6 nonsurvivors were not different with regard to age, ejection fraction, extent of coronary artery narrowing and time to first defibrillation. However, degeneration to VF within 30 seconds of arrest (5 of 6 nonsurvivors and 1 of 6 survivors, $p = 0.04$) and a slower rate of VT at the onset of arrest (166 beats/min in nonsurvivors and 227 beats/min in survivors, $p = 0.02$) were associated with unsuccessful resuscitation.

(Am J Cardiol 1985;56:588–592)

Despite the high prevalence of sudden cardiac death, few patients have had a cardiac arrest while wearing an ambulatory electrocardiographic (Holter) recorder such that the initiating cardiac arrhythmia and the period immediately before this arrhythmia can be accurately described. The Cardiac Arrhythmia Clinic at The Johns Hopkins Hospital serves as a referral center for the evaluation and treatment of ventricular tachycardia (VT) and ventricular fibrillation (VF). During the past 3 years, 13 patients have had an in-hospital cardiac arrest while wearing a Holter recorder. All patients were ambulatory on an inpatient ward and had not suffered a recent myocardial infarction. When we reviewed these continuous electrocardiographic (ECG) tracings, we wanted to find answers to 3 questions. First, is there an increase in the number of runs of VT in the hours before a cardiac arrest? Second, is VT rather than VF the initial arrhythmia at the time of cardiovascular collapse? Third, are there clinical, angiographic or arrest arrhythmia findings that correlate with successful resuscitation?

Methods

Patient selection: All patients in this retrospective study met 4 entry criteria: (1) each had a history of prior cardiac arrest or syncope and were admitted to hospital for evaluation and treatment; (2) all had an ambulatory ECG recorder in place during cardiac arrest and cardiopulmonary resuscitation and defibrillation were performed on all patients; (3) no patient had sustained an acute myocardial infarction during the 10 days before the cardiac arrest; and (4) there was no evidence of any new myocardial injury that might be responsible for the cardiac arrest. Except for 1 patient, all were undergoing telemetric monitoring such that the arrest was immediately recognized and resuscitation promptly started.

Ten of 13 patients underwent coronary arteriography (9 patients) or postmortem examination (1 patient), which allowed definition of the underlying structural heart disease. For patients with coronary heart disease, the extent of disease was assessed by the number of coronary arteries or major branches narrowed at least 70% in diameter. Left ventricular ejection fraction was determined in each patient by contrast angiography or gated cardiac blood pool scan.

Ambulatory electrocardiographic analysis: Delmar 445B 2-channel ambulatory ECG recorders (Delmar Avionics)

were used. Tapes were scanned by a Trendsetter electrocardioscanner analysis system. Quantitative counts of VT runs and the arrest sequence were checked by visual inspection of the tracings.

VT was present when at least 3 ventricular ectopic complexes occurred at a rate of at least 120 beats/min. VF was present when the ventricular wave pattern became disorganized and grossly irregular (Fig. 1 and 2). R-on-T phenomenon was defined as an ectopic ventricular complex with a prematurity index (R-R′/QT) of 1 or less.

The ambulatory ECG recording was separated into 4 periods for analysis: (1) the arrest sequence, (2) the hour immediately preceding arrest, (3) the 6-hour interval from 7 hours to 1 hour before the arrest, and (4) any recording more than 7 hours before the arrest. The arrest sequence was examined to determine how often an R-on-T ventricular premature beat was the initiating beat of the arrest arrhythmia, the nature of the initial arrhythmia at the beginning of the arrest, the rate and duration of the initial arrhythmia, whether it changed to another arrhythmia and the elapsed time from initial arrest arrhythmia to the first defibrillation. Finally, we noted whether sinus rhythm was reestablished and if the patient survived resuscitation.

In analyzing the time before arrest, the number of runs of VT during each of the 3 periods before the arrest was determined. The heart rate of the last 3 beats immediately before the arrest was calculated. A corrected QT interval for the complexes immediately before arrest was calculated for each patient using the Bazzett equation[1,2]: $QTc = QT/\sqrt{R\text{-}R'}$. For this study, a corrected QT interval longer than 0.42 second for men and longer than 0.43 for women was considered prolonged.

Statistical methods: Continuous data are reported as mean values ± standard error of the mean. Differences between the means of independent observations were assessed by an unpaired Student t test. Analysis of survival after arrest was by Fisher's exact test. Analysis of the increase in VT in the hours before arrest was by a nonparametric t test. Significance was established at a value <0.05.

Results

Clinical findings: The mean age of the patient group was 55 ± 4 years (range 22 to 83). Before admission to the hospital, 8 patients had a history of cardiac arrest and 5 patients had a syncopal episode considered secondary to a ventricular tachyarrhythmia. Ten of the 13 patients had had congestive heart failure that had been successfully treated by medications. Two of the 13 patients had a prior unmonitored in-hospital arrest. Ten patients had coronary artery disease and all 10 had survived at least 1 acute myocardial infarction. At coronary arteriography, 2 patients had 1-vessel coronary disease, 1 patient had 2-vessel disease and 4 patients had 3-vessel disease. Two patients had idiopathic dilated cardiomyopathy. One patient had no recognizable structural heart disease. Three patients with prior infarction did not undergo arteriography but were presumed to have coronary disease. The mean ejection fraction for the entire group was 23 ± 5% (range 7 to 67%).

The antiarrhythmic medications being used at the time of the recorded cardiac arrest were: procainamide (2 patients), procainamide and lidocaine (1 patient), aprindine (2 patients), flecainide (4 patients) and amiodarone (1 patient); 3 patients were not receiving antiarrhythmic medication. All medication was started after admission to hospital. No patient was receiving vasopressors or other medications that could have enhanced the appearance of a cardiac arrhythmia. Seven patients were taking digitalis, but none had serum levels above the therapeutic range. Serum potassium levels were normal in all patients. No patient complained of chest pain before arrest and none of the survivors of the arrest had ECG or cardiac enzyme evidence of myocardial injury.

Arrhythmia at time of cardiac arrest: VT was the initial arrhythmia at time of cardiac arrest in 12 patients. One patient had bradycardia followed by immediate VF. Examples of the arrhythmias are shown in Figures 1 and 2. No patient had ventricular asystole as the initial arrest arrhythmia. The initial VT rate was 203

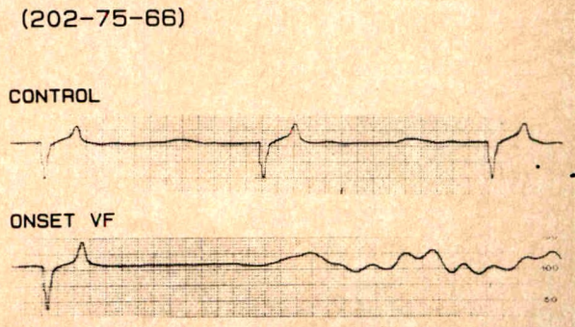

FIGURE 2. Cardiac arrest arrhythmias as recorded by a Holter monitor. Onset of ventricular fibrillation (VF) at the instant of cardiac arrest for patient JS.

TABLE I Electrocardiographic Findings at Cardiac Arrest

Pt	VT Runs/Hour Before Arrest			Heart Rate (beats/min) Before Arrest			
	Period 1 (>7 hr)	Period 2 (7 → 1 hr)	Period 3 (1 → 0 hr)	Period 3	Last 3 Beats	Initial VT Rate	Max VT Rate
WC	1	1	4	125	120	240	240
JJ	0.2	0	35	61	70	120	120
FK	0.5	0	16	76	80	180	180
BD	0	0	0	100	70	250	280
JP	0	0	1	89	120	180	240
JW	0.3	0.3	1	77	120	207	240
CF	1	25	147	63	50	210	270
FS	79	3	66	110	110	120	120
MR	0	2	31	68	100	200	200
JS	NR	0	0	110	36	VF	VF
ST	NR	0.3	4	68	120	280	300
JH	NR	0.2	2	90	60	240	330
RE	NR	NR	8	60	40	210	240

All values are mean values.
NR = no recording; VF = ventricular fibrillation; VT = ventricular tachycardia.

± 15 beats/min (range 120 to 280). The maximal VT rate was 232 ± 20 beats/min (range 120 to 330) (difference not significant) (Table I). VT degenerated to VF in 10 of the 12 patients when the initial arrhythmia was VT. The mean duration of VT before degeneration to a grossly disorganized rhythm considered to be VF for these 10 patients was 96 ± 31 seconds (range 5 to 300) (Fig. 3). Two patients had VT throughout the arrest. In no instance did VF spontaneously convert to VT.

Electrocardiographic recording before arrest: The number of VT runs per hour in the 3 periods before cardiac arrest is shown in Table I. Two patients had no VT before their arrest. Ten of 11 patients with VT before arrest had more VT runs in the hour immediately preceding the arrest ($p = 0.004$). For this analysis, periods 1 and 2 were compared with period 3. No patient had a decrease in the number of VT runs in the hour before arrest.

Ten of 13 patients had R-on-T phenomenon during the hours before arrest, but only 2 patients had it as the initiating beat of the arrest arrhythmia. Seven patients had a prolonged QTc interval. Of these patients, 2 were receiving flecainide (QTc = 0.43 and 0.46), 2 were receiving aprindine (QTc = 0.54 and 0.67), 1 patient was receiving procainamide (QTc = 0.56) and 2 were receiving no antiarrhythmic medications (QTc = 0.56 and 0.53).

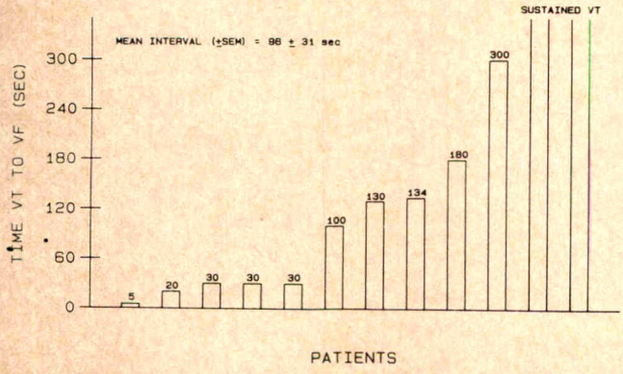

FIGURE 3. Conversion of ventricular tachycardia (VT) to ventricular fibrillation (VF) during cardiac arrest. Interval between onset of arrest VT and conversion of VT to VF is shown for each patient (JS excluded). SEM = standard error of the mean.

Outcome after cardiac arrest: Analysis of outcome after cardiac arrest was limited to the 12 patients undergoing telemetric monitoring who received prompt resuscitation. Six of these 12 patients survived and 6 did not. Several factors were examined to determine whether any clinical, anatomic or electrocardiographic findings were associated with a successful resuscitation (Table II). Survivors and nonsurvivors were examined with respect to the conduct of the resuscitation. There was no apparent difference in the drugs given, the presence of a palpable pulse, effectiveness of sternal compression, attempt at right ventricular overdrive pacing or endotracheal intubation. There was no difference in the interval from cardiovascular collapse to the first attempted defibrillation (Table II). Although survivors had a better ejection fraction (29%) than nonsurvivors (17%), the difference was not significant. There was no difference in the extent of coronary disease.

One difference between survivors and nonsurvivors was the duration of VT during the arrest before it degenerated to VF. In 5 of 6 nonsurvivors, VT deteriorated to VF in less than 30 seconds or VF was the initial arrest arrhythmia. In 5 of 6 survivors, progression of VT to VF was either delayed by more than 30 seconds or VT persisted and was the only arrhythmia during the arrest. This difference in the duration of VT between survivors and nonsurvivors was significant ($p = 0.04$) (Table II). A second and surprising difference was the initial rate of VT. Nonsurvivors had a slower initial rate of VT than survivors (Table II). The patient with immediate bradycardia and VF was not included in this analysis.

Discussion

Most information concerning arrhythmias during cardiac arrest is based on either studies of infarct patients monitored in a coronary care unit[3] or the first rhythm recorded by a life-support team at an out-of-hospital arrest.[4–6] Such studies are primarily biased toward periinfarctional arrhythmias and the findings

TABLE II Factors Influencing Resuscitation After Cardiac Arrest

Pt	Age (yr)	Multivessel Disease (70%)	EF (%)	QTc (sec)	Digoxin	Initial VT Rate (beats/min)	VT → VF in ≤30 sec	Time to 1st Defib (sec)

may not be representative of patients with recurrent sudden death and no infarction.

Arrhythmias at time of cardiac arrest: VT initiated the arrest sequence in 12 of 13 patients (92%) and then degenerated to VF in 10 (83%) of these 12. This appears to be the most common sequence of arrhythmias during cardiac arrest. Sixty-three cases of cardiac arrest occurring during 24-hour ambulatory ECG recording have been reported previously[7–10]; in 47 (74%) VT was the initial arrest arrhythmia and in 9 (14%) it was VF, 6 patients (9%) had profound bradycardia and 1 patient (2%) had asystole. Of the 47 patients with VT, in 37 (78%) the rhythm degenerated to VF.

Three reasons may explain the discrepancy between the high prevalence of VT as the initial arrest arrhythmia in our series and the findings of others that VF was the first recorded arrhythmia at out-of-hospital arrests.[4–6] First, there is an inherent delay between cardiovascular collapse outside hospital and arrival of a life-support team when an ECG rhythm strip can be recorded. In our study VT rapidly deteriorated to VF (mean 96 seconds). Thus, many patients with out-of-hospital arrest found in VF probably had VT as their first arrhythmia. Second, VF is the most common initial arrhythmia at the time of cardiac arrest during acute myocardial infarction.[3,11] Approximately 50% of out-of-hospital cardiac arrest patients are subsequently found to have new myocardial injury.[4,12,13] No patient in our report had chest pain before their arrest and none of the 6 survivors had ECG or cardiac enzyme changes to suggest new myocardial injury at the time of arrest. Third, the antiarrhythmic therapy that 10 of our 13 patients were receiving may be responsible for a higher proportion of patients having VT instead of VF as the initial arrest arrhythmia.

Increasing ventricular tachycardia during the hour before arrest: We confirm the findings of others that a significant increase in the frequency of VT runs occurs in the hours preceding a cardiac arrest. Pratt et al[7] (15 patients reported) and Lewis et al[8] (12 patients reported) both noted a significant increase in the frequency of VT runs in the 3 hours before arrest. Nevertheless, it should be noted that 11 of 40 patients (27%) in these 3 studies had no VT during the 3 monitored hours before arrest. Any arrhythmia detection device designed to warn against an impending arrest would not have identified these patients by an increase in the number of VT runs. Also, it is not known how often a substantial increase in VT runs occurs but is not followed by cardiac arrest.

Failure to resuscitate: We are concerned why resuscitation efforts were not more successful in our patient series despite prompt assistance and defibrillation. No previous study has examined whether clinical, angiographic and electrocardiographic variables are associated with successful resuscitation of patients who have had a cardiac arrest. Weaver et al[14] reported the follow-up of 64 patients who had coronary angiography soon after resuscitation from out-of-hospital arrest. They found that the ejection fraction of 14 patients who later died suddenly or had another episode of VF was significantly lower than that of those who had no further arrhythmic event (39% vs 51%). We did not find a correlation between left ventricular dysfunction and successful resuscitation, nor did we find a higher proportion of patients with multivessel disease among nonsurvivors. The duration of VT was different between survivors and nonsurvivors. Progression from VT to VF in less than 30 seconds was associated with an unsuccessful resuscitation effort. Conversely, if VT persisted or there was a delay of more than 30 seconds before VT degenerated to VF, patients had a greater chance of successful resuscitation. Rapid degeneration to VF may reflect a greater degree of electrical disorganization that is more difficult to correct.

Clinical significance: Because these patients had been referred to our hospital after a prior out-of-hospital cardiac arrest or syncope, our presumption is that the in-hospital arrhythmic findings would be similar to those found at the time of an out-of-hospital cardiac

arrest if ambulatory ECG recordings had been available. Because VT and VF are the 2 arrhythmias most often found at the time of a cardiac arrest, recognition of both arrhythmias is necessary for any detection or defibrillation device. An implantable device that recognizes both arrhythmias has been successfully used.[15] Pacemaker capability appears less important because profound bradycardia or asystole as the probable mechanism of cardiac arrest occurs in less than 10% of patients.

Acknowledgment: We gratefully acknowledge the ambulatory ECG assistance of Joseph Wassil and Donald Liggins, the secreterial help of Nancy Grap and the editorial review by Dr. Myron Weisfeldt in the preparation of this manuscript.

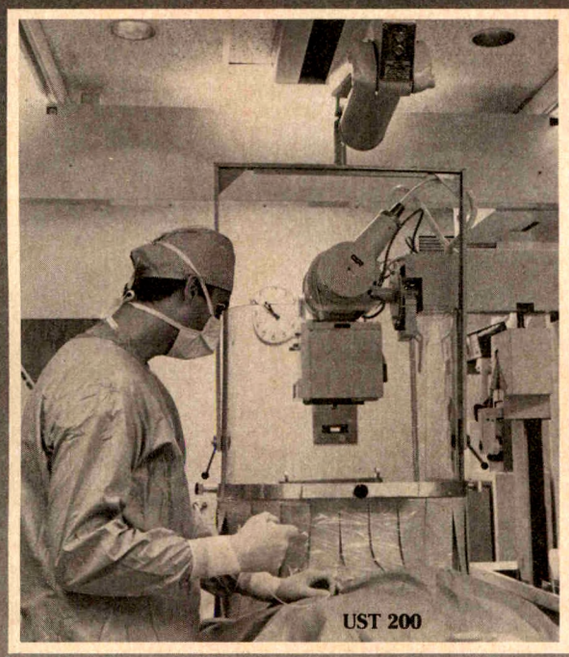
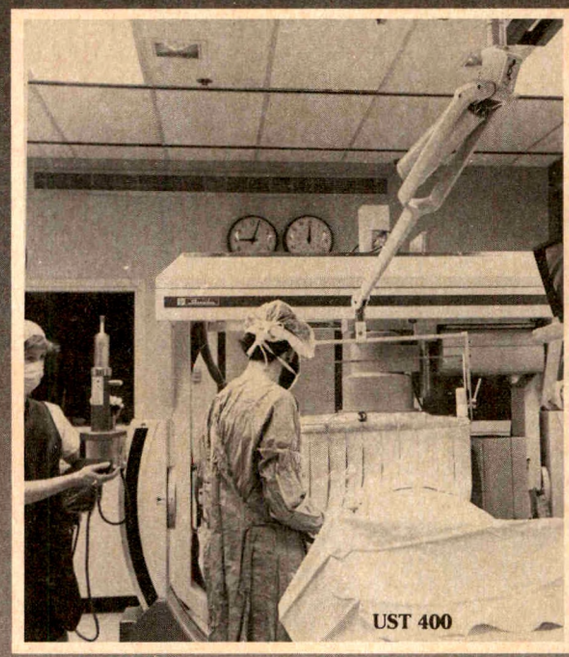
A Radiation Protective Shield for Interventional Radiology

"Provides protection from patient scatter during lengthy fluoroscopic procedures without interfering with the performance of the examination"



UST 200



UST 400

Patent Pending

The growing concern for radiation protection during modern theraputic fluoroscopic techniques for embolizations, abscess drainage, biliary drainage, cardiac catheterizations and other lengthy procedures has created a universal need for protective devices to shield harmful patient scatter.

The UST Interventional Shield, which is positioned close to the x-ray source, effectively reduces scatter radiation to less than 0.1 mr/hr, offering the maximum protection to the eyes, thyroid and complete upper torso of staff employees performing the procedure, while allowing total freedom of movement around the work area.

FEATURES:

- Lead acrylic patient observation panel (0.5mm to 1.0mm lead equivalency)
- Double split lead/vinyl patient forming curtain (1.0mm total lead equivalency) with disposable sterilized clear plastic sleeves
- Detachable aluminum positioning handles for autoclave use
- Dual pivotal locking devices
- Counter balanced ceiling suspension system and track assembly with 202 centimeters of horizontal travel

Also available for "C" and "U" - ARM type apparatus

ENDOWED CHAIR IN CARDIOLOGY:

The Department of Medicine of the University of Florida College of Medicine is seeking application for an endowed Chair in Cardiology. The endowed Chair, with assets in excess of one million dollars, was established by the State of Florida's Eminent Scholars Program and was made possible by generous contributions from the Palm Beach-Martin County Heart Association. The individual who will fill the Chair will have a full-time faculty appointment (Professor) in the Division of Cardiology of the Department of Medicine of the University of Florida College of Medicine. The appointee should have an M.D. degree and a major commitment to and substantial skills in teaching in clinical cardiology. Salary is negotiable. Anticipated starting date is July 1, 1986. Interested individuals should write by February 28, 1986: James E. McGuigan, M.D., Chairman, Search Committee, Chair in Cardiology, Department of Medicine, Box J-277, University of Florida Health Center, Gainesville, FL 32610. The University of Florida is an Equal Opportunity/ Affirmative Action Employer.

CARDIOLOGIST NEEDED: Board certified/eligible cardiologists with invasive and noninvasive training needed in multispecialty HMO expanding into Stockton and South Sacramento. University of California, Davis affiliation. Must have California license. Send curriculum vitae to Robert Midgley, Jr., M.D., The Permanente Medical Group, Inc., 6600 Bruceville Road, Sacramento, California 95825.
An Equal Opportunity Employer.

CARDIOLOGIST—Progressive, university affiliated New England community hospital seeking state-of-the-art trained interventional cardiologist to develop angioplasty program, direct cardiac cath lab and be Assistant Chief of Cardiology. Outstanding opportunity to direct, teach, practice and do clinical research in rewarding environment. Reply with C.V. to Box 450, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

BC/BE Cardiologist wanted to join 2 BC Cardiologists in busy, quality practice, Phila. Full non-invasive plus SG, pacers, and EP if qualified. Academic affiliation. Prefer U.S. trained. Send CV & references to Box 440, The American Journal of Cardiology, 875 Third Ave., New York, N.Y. 10022.

CARDIOLOGIST

To join consultative cardiology practice for large referral area. Training in cardiac catheterization, PTCA and noninvasive mandatory. Located in South. Send C.V. and details about your interests to Box 435, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

Either way, no other system gives you all this flexibility in such a compact, affordable package.

- User selectable formats—chart out either 3 or 6 channels to meet your specific needs
- Computer memory allows you to acquire and store digital data simultaneously from all 12-leads; exact same cardiac cycles, increasing confidence in interpretation
- Large LCD for monitoring up to three operator selectable channels of ECG. Heart rate, time and date are conveniently displayed
- Built-in self diagnostics alert the operator of potential problems
- Exceptional reliability and compact design through use of state-of-the-art robotics and surface mount technology during manufacture
- Choose from four models to meet your exact requirements

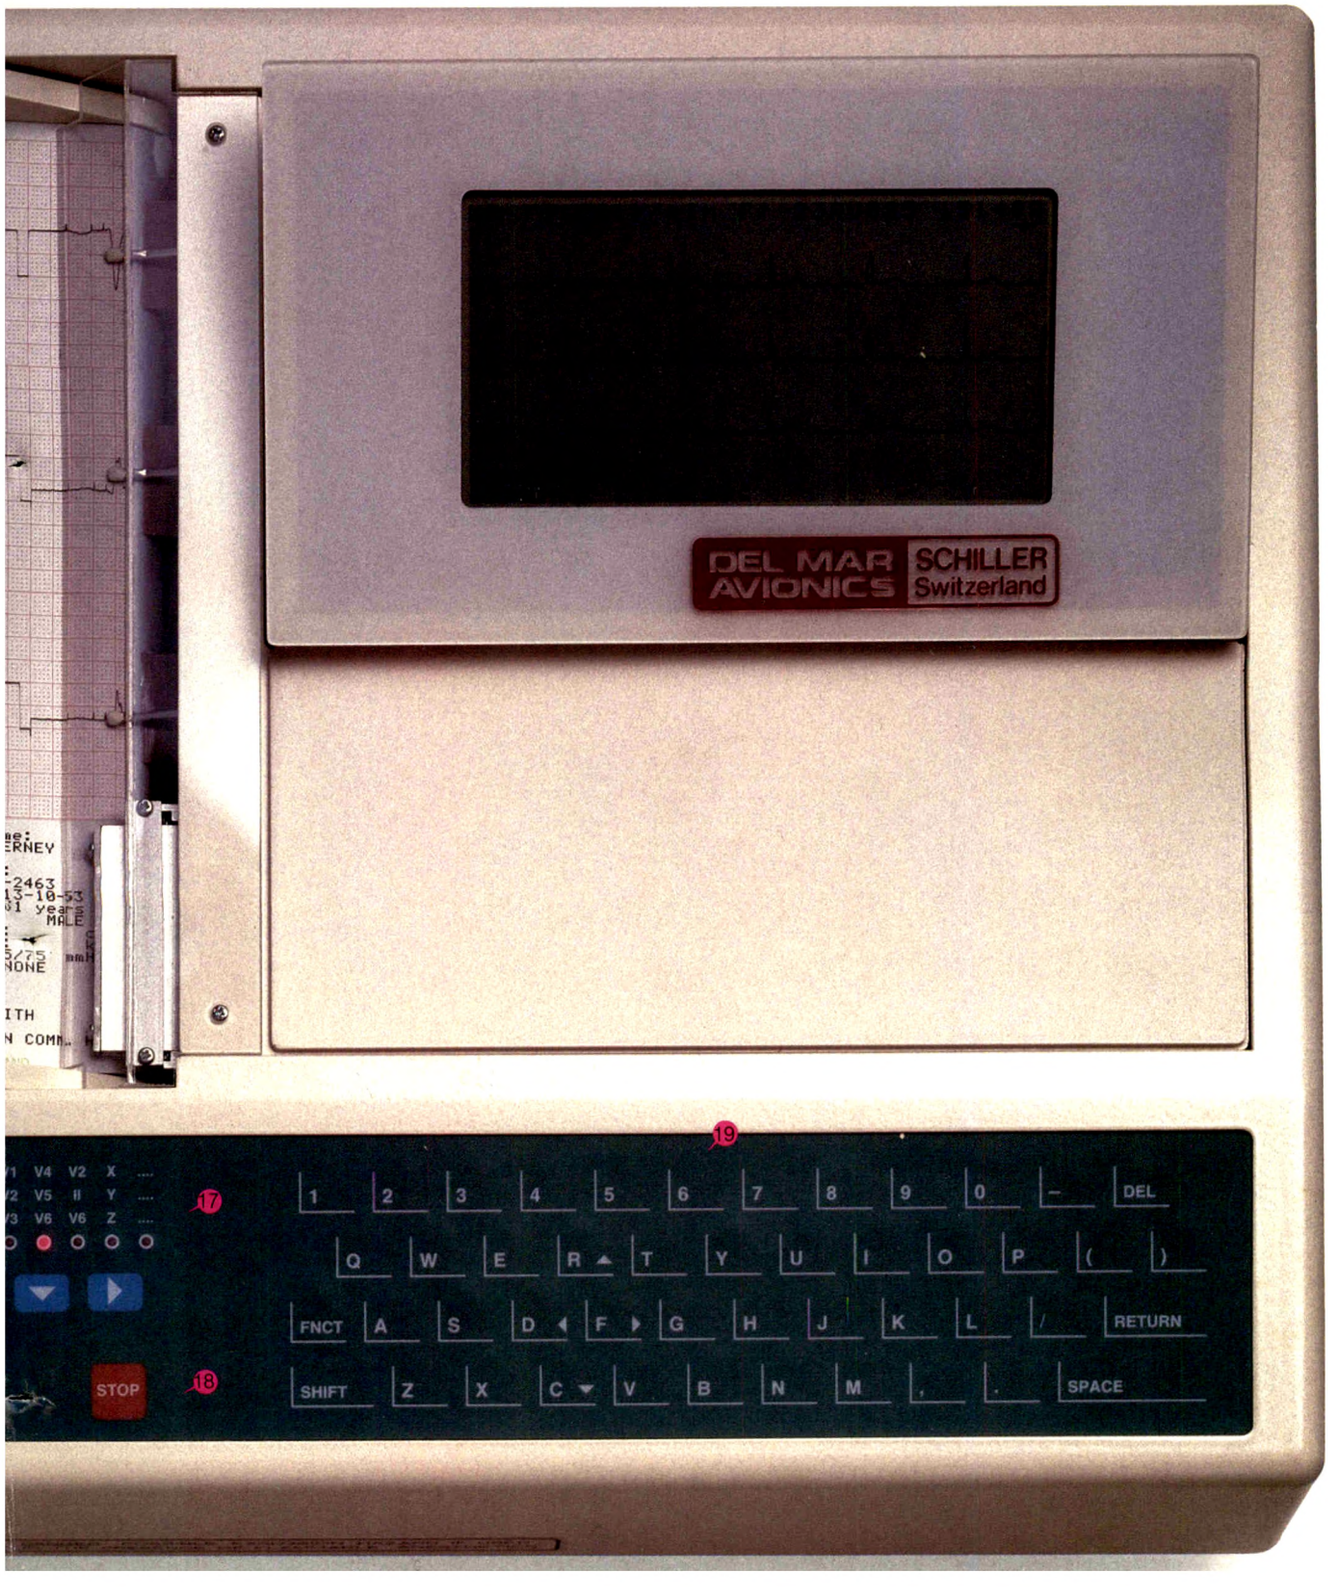

Chart out your ECG in virtually any format.

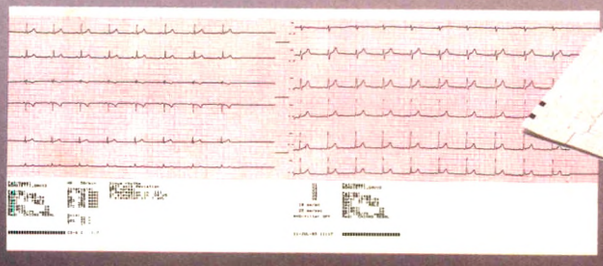
- Automatic or manual mode
- 3-channel chart out, 2.5 or 5 seconds of activity per lead group, marked average complexes and diagnostic interpretation
- 6-channel chart out, 5 or 10 seconds of activity per lead group, marked average complexes and diagnostic interpretation
- Rhythm strip capability from any of 14 preprogrammed lead groups
- Variable chart speeds: 2.5mm, 5mm, 10mm, 50mm or 100mm
- With or without average cycles to verify data. Representative QRS complexes are marked where measurements are made
- 5mm/mV, 10mm/mV, 20mm/mV, 40mm/mV sensitivity
- Enlarged waveforms for more detailed examinations
- Duplicate ECG recordings
- Final reports



Shown is a six-channel, two-page format. In this mode, a full ten-second, simultaneous tracing of all 12 leads is produced—eliminating the need for a separate rhythm strip.

Usefulness of Programmed Stimulation in Predicting Efficacy of Propafenone in Long-Term Antiarrhythmic Therapy for Paroxysmal Supraventricular Tachycardia

MATTHIAS MANZ, MD, GERHARD STEINBECK, MD, and BERNDT LÜDERITZ, MD

The electrophysiologic effects of intravenous (i.v.) and oral propafenone were evaluated in 14 patients with Wolff-Parkinson-White syndrome and in 10 patients with atrioventricular (AV) nodal reentrant tachycardia. The effective refractory periods of the right atrium and the AV node increased after both preparations. In patients with Wolff-Parkinson-White syndrome, i.v. propafenone blocked anterograde accessory pathway conduction in 2 patients and retrograde conduction in 1; during oral therapy, accessory pathway conduction block occurred in 2 additional patients. The mean cycle length of the supraventricular tachycardia (SVT) increased from 338 ± 60 ms to 387 ± 56 ms ($p < 0.05$) after i.v. application, and from 336 ± 65 ms to 367 ± 65 ms ($p < 0.05$) during oral propafenone. The shortest pacing interval maintaining a 1:1 AV conduction increased from 325 ± 65 ms to 368 ± 81 ms ($p < 0.05$) after i.v. infusion, and from 333 ± 57 ms to 369 ± 75 ms ($p < 0.05$) during oral therapy. There was no difference in the electrophysiologic effects between i.v. and oral propafenone. The induction of SVT was prevented by i.v. propafenone in 10 of 20 patients and in 4 additional patients with oral propafenone. During follow-up, 6 of 7 patients, whose SVT could not be initiated by electrophysiologic drug testing, remained free from recurrences, whereas 5 of 7 patients with inducible tachycardia had recurrences of SVT. Thus, in patients with SVT, propafenone prolonged accessory pathway and AV nodal conduction and had a beneficial effect on circus movement tachycardia. Electrophysiologic drug testing with propafenone predicts its efficacy during chronic therapy in most patients.

(Am J Cardiol 1985;56:593–597)

Propafenone hydrochloride decreases the maximal rate of increase of the action potential, and shortens the action potential duration in atrial and ventricular structures of the heart; therefore, it belongs to the class I antiarrhythmic agents.[1–3] Previous studies showed that propafenone is effective for control of supraventricular and ventricular arrhythmias.[4–7] Electrophysiologic investigations for the evaluation of propafenone in patients with supraventricular tachycardia (SVT) are limited[8–12]; only a few patients have been studied during oral therapy.[9,11] The present study evaluates the influence of propafenone on the electrophysiologic properties in patients with Wolff-Parkinson-White (WPW) syndrome and with atrioventricular (AV) nodal reentrant tachycardia after intravenous (i.v.) application; it also determines whether acute electrophysiologic drug testing can predict the efficacy of propafenone during oral therapy in patients with SVT.

Methods

Patients: In 24 patients (8 women and 16 men, aged 12 to 70 years), diagnostic investigations were performed. The patients were studied in the nonsedated state and did not receive cardioactive drugs for at least 48 hours before the investigation. Each patient gave an informed written consent. All patients had 8 ± 6 episodes (range 2 to 24) of sustained SVT in the 12 months before entrance into the study. Previous antiarrhythmic therapy included 2.5 ± 1 antiarrhythmic agents (range 1 to 4) in 22 cases; 2 patients had no previous antiarrhythmic treatment.

Electrode catheters were inserted through the right femoral and left basilic vein, and were placed into the right atrium, right ventricle, coronary sinus and just below the tricuspid valve to record the His bundle activity. Electrocardiographic leads I, II and V_1 and 3 bipolar intracardiac leads were recorded simultaneously. Atrial and ventricular stimulation were performed using the single-test stimulus method as well as regular pacing at increasing rates. Effective refractory pe-

riods of the accessory pathway and of the AV node were both obtained with a basic stimulation rate of 100/min using the single-test stimulus method. The mean cycle length during reentrant tachycardia and the shortest atrial interval during incremental atrial pacing were compared with the results after drug treatment.[12] The following criteria for diagnosis of AV nodal reentrant tachycardia were used: (1) induction of SVT related to a critical AH delay with both incremental pacing and atrial extrastimulus testing; (2) demonstration of anterograde dual AV nodal pathway; (3) atrial activation occurring before or simultaneously with the onset of ventricular activation during SVT; and (4) normal retrograde atrial activation sequences during SVT. Retrograde anomalous pathway conduction during SVT was proved by the following criteria: (1) abnormal retrograde atrial activation sequence; and (2) ability to capture the atria during SVT with critically timed ventricular extrastimuli when the His bundle was refractory.[13–15]

After the initial electrophysiologic study, 1 mg/kg of propafenone was administered intravenously over 5 to 10 minutes. After a 5-minute period of drug distribution, the electrophysiologic protocol was repeated. In 14 patients, who underwent a second electrophysiologic study, the stimulation protocol was repeated after 5 to 7 days of oral therapy with 150 mg of propafenone 3 to 4 times daily; 1 patient received 150 mg 5 times daily. The study was performed 1 to 2 hours after the last dose was administered. Seventeen patients continued receiving oral therapy with propafenone and were followed on an out patient basis at 4- to 8-months intervals.

Group data are presented as mean ± standard deviation of the mean. Friedman's analysis of variance by ranks and Wilcoxon matched-pairs signed-ranks test were used.

Results

Patterns of WPW syndrome were present in 14 patients, including 4 patients with concealed anterograde accessory pathway conduction. The electrophysiologic study revealed a right-sided accessory pathway in 2 patients, a left-sided pathway in 7 and a septal pathway in 4 (no localization in 1 patient). AV nodal reentrant tachycardia could be demonstrated in the remaining 10 patients.

Atrial and ventricular refractory periods: The effective refractory periods of the right atrium increased from 210 ± 24 ms to 225 ± 29 ms ($p < 0.05$) after i.v. application, and from 212 ± 23 ms to 228 ± 41 ms during oral therapy ($p < 0.05$). The effective refractory periods of the right ventricle were unaffected by propafenone (i.v.: control 236 ± 20 ms, propafenone 236 ± 22; oral: control 239 ± 21 ms, propafenone 246 ± 22 ms).

Accessory pathway properties: The influence of propafenone on the effective refractory period of the accessory pathway is listed in Table I. After i.v. propafenone, anterograde conduction of the accessory pathway was blocked in 2 patients, and retrograde conduction in 1 patient. During oral therapy, 2 additional patients had a block of accessory pathway conduction, 1 in the anterograde and 1 in the retrograde direction. The anterograde effective refractory periods of the remaining patients increased in 4, remained unchanged in 3 and decreased in 1 patient. Retrograde effective refractory periods were determined by the refractoriness of the ventricle in 8 patients; therefore, accessory pathway effective refractory periods could not be measured in these cases. In the remaining patients, prolongation of the effective refractory periods was found. The shortest atrial intervals with 1:1 AV conduction during incremental atrial pacing are given in Figure 1. After i.v. administration of propafenone, the intervals increased from 325 ± 65 ms to 368 ± 81 ms ($p < 0.05$). During oral therapy, an increase from 333 ± 57 ms to 369 ± 75 ms was observed ($p < 0.05$).

Atrioventricular node: Table II is a summary of the effects of propafenone on the effective refractory periods of the AV node for both anterograde and retrograde conduction. There was an increase in the effective refractory periods after i.v. and oral propafenone in most patients. Retrograde conduction of patient 4 was blocked after i.v. and oral propafenone.

Reentrant tachycardia: Intravenous propafenone increased the mean cycle length of the induced reentrant tachycardia from 338 ± 60 ms to 387 ± 56 ms ($p < 0.05$). A similar increase of the mean cycle length from 336 ± 65 ms to 367 ± 65 ms was noted during oral drug treatment ($p < 0.05$, Fig. 2). Induction of reentrant

tachycardias could be estimated in 20 patients during control and after infusion of propafenone. Two patients had only paroxysmal atrial fibrillation; no tachycardia could be initiated in 1 patient and persistence of atrial fibrillation terminated the study in 1 other patient. Intravenous administration of propafenone prevented induction of reentrant tachycardias in 10 patients. The echo zone of induction was unchanged in 7 patients, smaller (>20 ms) in 2 and wider (>20 ms) in 1. During oral therapy, the inducibility of the reentrant tachycardia returned in 1 patient (Fig. 3). On the other hand, the induction of sustained reentrant tachycardia was no longer possible in 4 other patients during oral therapy; in 2 of these 4 patients, 5-beat runs of nonsustained tachycardia were recorded.

Patient follow-up: After discharge from the hospital, 17 patients continued oral therapy with 557 ± 70 mg of propafenone. Three of these patients left the study: 1 patient was referred for cardiac operation because of pulmonary stenosis together with corrected transposition of the great arteries, and died within 1 month; 1 died of bronchial cancer after 4 months without SVT recurrence; and 1 was lost to follow up because he re-

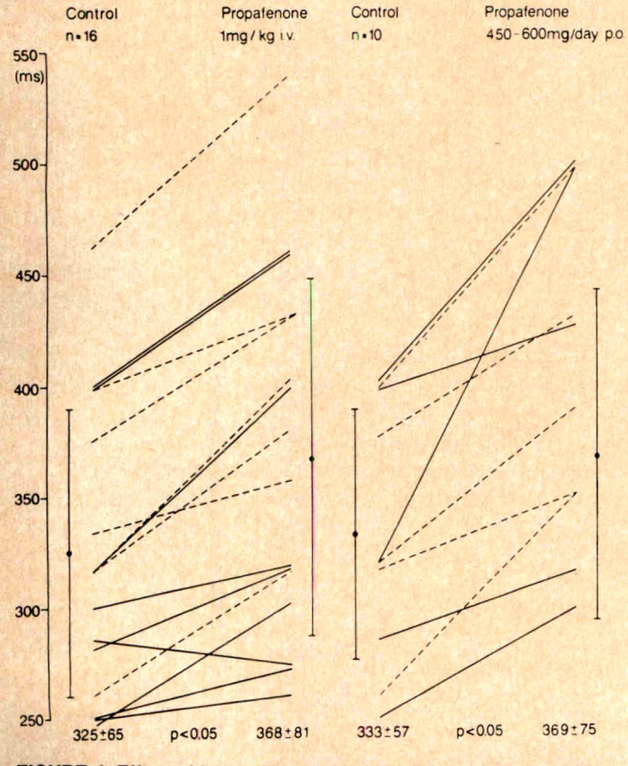

FIGURE 1. Effect of intravenous (i.v.) and oral (p.o.) propafenone on the shortest atrial intervals with 1:1 atrioventricular conduction during atrial incremental pacing in patients with Wolff-Parkinson-White syndrome (**solid line**) and atrioventricular reentrant tachycardia (**broken line**).

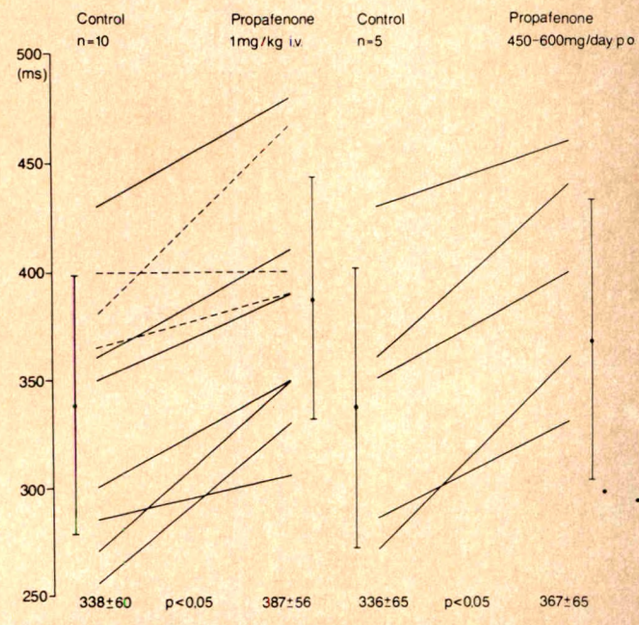

FIGURE 2. Effect of intravenous (i.v.) and oral (p.o.) propafenone on the mean cycle length of induced supraventricular reentrant tachycardia in patients with Wolff-Parkinson-White syndrome (**solid line**) and atrioventricular nodal reentrant tachycardia (**broken line**).

turned to his native country. Of the remaining patients, 2 were treated with amiodarone because of recurrent atrial fibrillation, 3 received β-blocker therapy and 2 had no long-term antiarrhythmic therapy because they had a low incidence of SVT (2 in 12 months). Among the 14 patients who were treated during long-term patient management with propafenone, SVT in 7 patients (group 1) was controlled during electrophysiologic drug testing (both i.v. and oral treatment in 6 patients and oral treatment alone in 1 patient). In group 1, 6 of 7 patients remained free from recurrences for a mean of 25 ± 7 months. One patient reported 3 self-terminating SVTs in 30 months (control: 15 SVTs in 12 months) and continued to take the substance. Two patients in group 1 interrupted drug treatment for 2 and 3 months, experienced recurrences and started to take propafenone again. In group 2 patients, whose SVT was not controlled by i.v. (n = 5) and oral (n = 2) propafenone treatment during the electrophysiologic study, 5 had recurrences of SVT during a period of 18 ± 11 months. Two of these patients had only 1 and 2 recurrences per year and continued to take the drug. Three of the remaining patients had more frequent episodes of SVT (3 in 4 months, 5 and 7 within 12 months); these patients were treated with amiodarone. The incidence of SVT for the 2 groups was the same before entry into the study. The follow-up of group 2 was shorter because therapy in 3 patients was switched to amiodarone. Four patients complained about gastrointestinal side effects at the beginning of the oral therapy, but no patient had to discontinue propafenone.

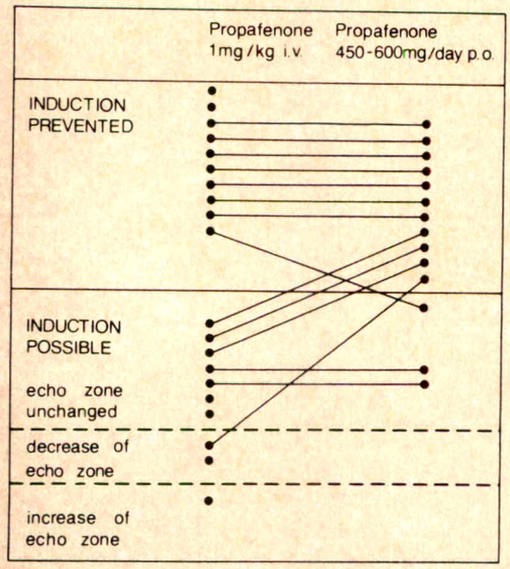

FIGURE 3. Inducibility of supraventricular reentrant tachycardia after intravenous (i.v.) and oral (p.o.) treatment with propafenone in 20 patients. Intravenous propafenone prevented the induction of the reentrant tachycardia in 10 patients (6 with atrioventricular [AV] nodal reentrant tachycardias, 4 with Wolff-Parkinson-White [WPW] syndrome). The electrophysiologic study could be repeated in 14 patients during oral therapy; in this cohort, reentrant tachycardias of 7 patients (5 with AV nodal reentrant tachycardias, 2 with WPW syndromes) were not inducible as before. In 4 additional patients (1 with AV nodal reentrant tachycardia, 3 with WPW syndromes), the tachycardia could not be initiated any longer; however, tachycardia returned in 1 patient with WPW syndrome.

Discussion

In our investigation, propafenone had a uniform effect on the refractoriness of the atrium, the AV node and accessory pathway in anterograde and retrograde direction. These results are in accordance with previous studies,[8–12] which reported a higher percentage of anterograde accessory pathway block, probably a result of the 1.5- and 2 mg/kg-dose of propafenone given. The prolongation of the refractory periods and the slowing of conduction resulted in a decrease of the heart rate during SVT and protected against rapid ventricular rates during atrial fibrillation.

The effect of i.v. propafenone on the refractory periods was of the same magnitude as the effect during oral treatment. With respect to the induction of SVT, some patients appeared to benefit additionally during oral drug trials. The slightly better results during oral treatment compared with i.v. application might have been caused by active metabolites such as 5-hydroxypropafenone.[17] In a previous study, the effects of i.v. and oral treatment with propafenone was demonstrated in a cohort of 5 patients.[9]

In the present study, patients with complete suppression of SVT at the electrophysiologic drug trial appeared to have less recurrences of SVT during long-term therapy. Effective prophylactic drug therapy could be predicted in most patients with WPW syndrome[18] or AV nodal reentrant tachycardia by serial electrophysiologic drug testing.[19] Recently Klein et al[20] reported that acute drug testing with verapamil could predict the response to long-term therapy with oral verapamil. These data support the assumption that the electrophysiologic drug trial can predict the efficacy of long-term therapy in most patients with SVT.

Limitations: The result of the electrophysiologic study may be influenced by the tone of the autonomous nervous system at the different days of the study. The electrophysiologic investigation could be repeated only in 14 patients and chronic propafenone therapy was continued only in two-thirds, resulting in patient selection. Tachycardiac attacks were assessed by the reports of the patients, but objective recordings were lacking.

Clinical implications: Propafenone had a uniform effect on AV node structures and on accessory pathway tracts, resulting in a decrease of the rate during reentrant tachycardias and during the atrial tachyarrhythmias. Propafenone proved an effective antiarrhythmic agent for long-term treatment of patients with SVT. Acute drug testing with propafenone can predict its effects during chronic therapy in most patients with SVT.

Effects of Atenolol on Exercise Capacity in Patients with Mitral Stenosis with Sinus Rhythm

HERMAN O. KLEIN, MD, PINHAS SARELI, MD, COLON L. SCHAMROTH, MB, FCP (SA), YOONOOS CARIM, MB, FCP (SA), MENASHE EPSTEIN, MD, and BRIDGET MARCUS, MBBCh

Exercise capacity is frequently impaired in patients with mitral stenosis (MS) and sinus rhythm (SR). The resulting increased heart rate, which shortens the diastolic filling period, and the increased cardiac output lead to further elevations of left atrial pressure and subsequent pulmonary congestion. The effect of the β-receptor blocking agent atenolol, 100 mg/day, was assessed in 13 patients with MS and SR. Exercise performance was assessed using a modified multistage Bruce protocol after 2 weeks of placebo and after 2 weeks therapy with atenolol in a single-blind, crossover, placebo-controlled, randomized study. Atenolol resulted in significant decreases in mean heart rates at rest and during exercise ($p = 0.0015$) and a significant increase in total exercise time ($p = 0.0015$). Maximal exercise capacity was also significantly improved ($p = 0.0015$). All patients were both objectively and subjectively improved by atenolol. Thus, β-blockade with atenolol improves exercise capacity in patients with MS and SR and may be of benefit to most such patients. The improved effort tolerance is attributed to reduction of the exercise-associated sinus tachycardia by β-blockade, allowing a longer diastolic filling period and better left atrial decompression. (Am J Cardiol 1985;56:598–601)

Exercise capacity is frequently impaired in patients with mitral stenosis (MS). The pressure gradient across the mital valve is directly related to the diastolic blood flow through the orifice and inversely related to the orifice size and duration of the diastolic filling period.[1–3] Any increase in cardiac output or decrease of the diastolic filling period, as occurs with tachycardia, produces an exponential rise in the pressure gradient.[3] The result is reflected clinically by dyspnea on exertion and, in severe cases, by the precipitation of pulmonary edema.

Intravenous administration of propranolol has been studied by catheterization and has a beneficial effect on hemodynamic values at rest[3–8] and during supine exercise.[6,7] D'Annunzio and Mobilij[8] showed hemodynamic improvement at rest after oral propranolol administration for 1 month in 5 patients with MS and sinus rhythm (SR). We found only 1 study that compared exercise capacity both before and after the chronic administration of β-blocking agents.[9] We studied 13 patients who had significant MS and were in SR. These patients were evaluated in a single-blind, placebo-controlled, crossover study. The β blocker selected for the study was the cardioselective agent atenolol.

From the Department of Cardiology, Baragwanath Hospital, and the University of the Witwatersrand, Johannesburg, South Africa. Manuscript received February 18, 1985; revised manuscript received April 23, 1985, accepted April 29, 1985.

Methods

Patients: Thirteen consecutive patients with isolated MS and SR were subjected to a prospective crossover, single-blind, placebo-controlled study. There were 11 female and 2 male patients, aged 15 to 35 years. All were in functional class II or III of the New York Heart Association classification. The diagnosis of MS was made clinically and confirmed by echocardiography in every patient. MS was considered significant in all 13 patients as judged by the echocardiographic finding of a mitral valve orifice area of less than 1.5 cm. All patients received oral diuretic therapy throughout the study period. All had evidence of pulmonary arterial hypertension, as judged by a palpable right ventricular impulse and a loud pulmonic component of the second heart sound. Chest roentgenographic and electrocardiographic findings were all compatible with the clinical diagnosis.

Study protocol: The 13 patients were subjected to a 2-phase, crossover study with each phase consisting of 2 weeks. Seven patients began with placebo and the other 6 with oral atenolol treatments, 100 mg taken in the morning. A β-blocker

effect was considered to be present if the heart rate at rest decreased by 10% or more from placebo to atenolol phases. The tablets of atenolol and placebo were identical in appearance. Serum atenolol concentration was measured in 3 patients chosen at random at the end of the 2-week atenolol phase.

Exercise protocol: The 13 patients underwent exercise testing on a commercial treadmill according to a modified Bruce protocol until the point of exhaustion, dizziness or severe dyspnea was reached.

The following measures of functional capacity were compared during placebo and atenolol phases: (1) heart rate and blood pressure at rest, at the end of each exercise stage and at the completion of exercise; (2) total duration of exercise; and (3) maximal exercise capacity index (expressed as work units). Maximal exercise capacity was derived from the following formula, which was calculated for each stage of exercise and then summated: [time (min) × speed (km/hr) × incline (degrees)/3 minutes]. For example, in a patient who completed stage 1 but managed only 2 minutes of stage 2: $[(3 \times 2.7 \times 1)/3 + (2 \times 2.7 \times 5)/3] = 11.7$ work units. This index, adapted from Redfors,[10] takes into account not only the total time spent exercising, but also the increasing difficulty of exercise with each successive stage.

Plasma atenolol concentration: Atenolol concentrations were measured at random in 3 patients. The plasma concentration of atenolol was determined by the procedure described by Yin-Gail et al.[11]

Statistical analysis: Wilcoxon's signed-rank test procedure was used for analysis of all variables.[12] This test was modified where applicable according to the method of Bonferroni.[13] A p value of <0.01 was considered significant.

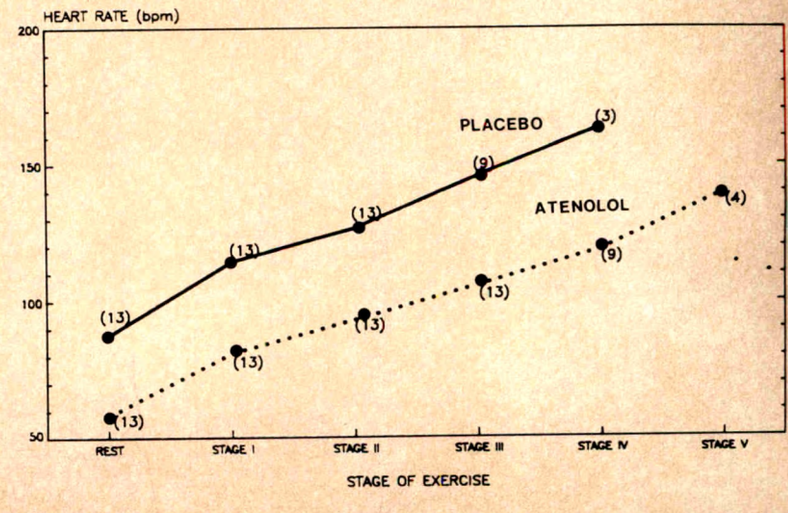

FIGURE 1. Mean heart rates at different stages of exercise during atenolol and placebo phases. **Brackets** indicate number of patients reaching a particular stage.

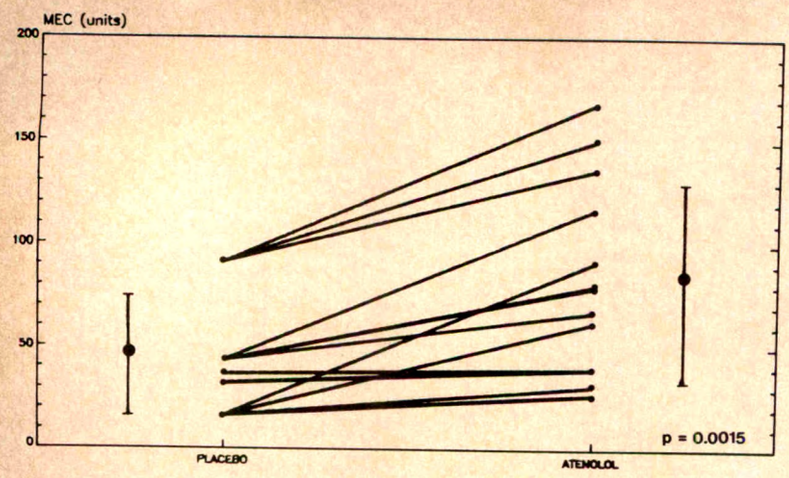

FIGURE 2. Maximal exercise capacity (MEC) during atenolol and placebo phases.

Results

Values at rest: Values measured at rest are listed in Table I. Mean heart rate at rest for the 13 patients was 88 ± 12 beats/min (range 57 to 100) during the placebo period, and decreased to 58 ± 8 beats/min (range 51 to 75) after 2 weeks of atenolol treatment ($p = 0.0015$). The mean decrease in heart rate at rest was 34%. Systolic and diastolic blood pressures did not change significantly.

Response to exercise: All individual and mean heart rates were significantly lower at each stage of exercise during atenolol treatment than during placebo (Fig. 1, Table I). Blood pressure values did not change significantly. The maximal exercise capacity and the total time spent on the treadmill increased significantly during the atenolol phase (Fig. 2 and 3, Table I).

Plasma atenolol concentration: The plasma atenolol concentrations in the 3 patients chosen at random were 193, 246 and 665 ng/ml (mean 368).

Discussion

The results of previous studies[3–8] reflecting acute hemodynamic changes in MS with SR strongly suggested that β-blocker administration on a long-term basis could improve exercise capacity. The only study that investigated this issue with oral therapy was not completely placebo-controlled and used a noncardioselective agent.[9] The present placebo-controlled study demonstrated that β blockade significantly improves exercise capacity in patients with MS and intact sinus node function. The results are similar to those of Penas et al.[9] The increase in exercise capacity is probably mediated by the negative chronotropic effect of β-blocking drugs on sinus node function, both at rest and in response to exercise. Effort dyspnea is reduced and the risk of exercise induced pulmonary edema is diminished.

Amery et al[14] showed that there is a clear relation between plasma atenolol concentration and percent reduction in exercise heart rate. The therapeutic plasma atenolol concentrations determined by these investigators (100 to 500 ng/ml) are similar to those obtained in the present study. In practice, the determination of plasma atenolol concentration is not necessary for the clinical management of compliant patients, although its availability permits the exclusion of placebo-related or conditioning effects. A decrease in heart rate of at least 10% at rest after a starting dose of 100 mg/day of atenolol is usually an adequate means of monitoring the compliance and clinical response of patients.

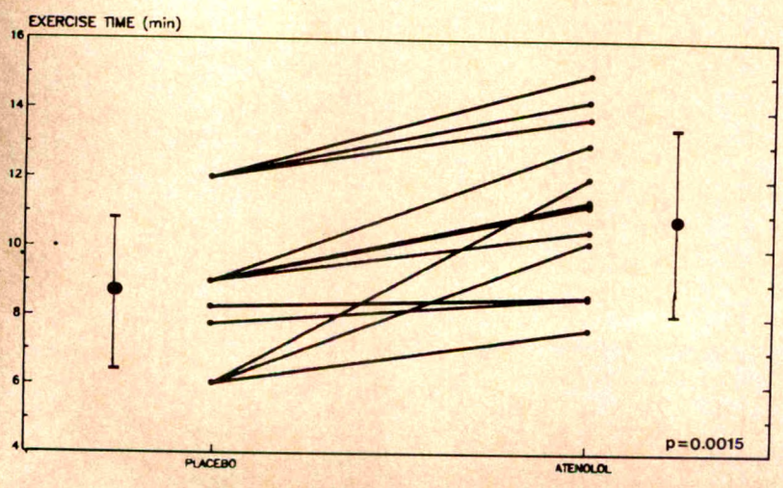

FIGURE 3. Exercise time during atenolol and placebo phases.

Physicians may be reluctant to use β-blocking drugs in patients with MS because of the negative inotropic effect of these drugs.[15,16] The deleterious effects of this action, however, in the context of MS without severe pulmonary arterial hypertension or evidence of right heart failure, is negligible.[4,5] The choice of atenolol was motivated by its easy (once a day) administration, as well as its long duration of action, cardioselectivity and hydrophilic properties. Although there is a potential and theoretical adverse effect of β blockade in reducing left atrial contractility, this effect was not evident in our patients or was negated by the advantageous effects of a slower heart rate.

Although the use of atenolol in pregnant and lactating women is limited, there is no evidence of teratogenicity, nor of neonatal or infant toxicity either in our experience or that of other investigators.[17–20] Outside of this study we have used atenolol in several pregnant women with MS without mishap.

Beta-blocking drugs should be administered cautiously when pulmonary arterial hypertension is marked, and their use may be contraindicated in some patients with MS and right ventricular failure.

The clinical application of this study is readily apparent. The long-term use of a β-blocking drug, such as atenolol will improve exercise capacity and allow the postponement of surgical intervention in many patients with significant MS.

Acknowledgment: We thank Joseph Di Nicola for technical assistance and the Photographic Unit, University of the Witwatersrand, Johannesburg, for the photographic reproductions.

The tablets of atenolol and placebo were kindly supplied by Imperial Chemical Industries, Inc.

Electrophysiologic Mechanisms of Provoked Atrial Flutter in Mitral Valve Prolapse Syndrome

DAVID J. DOBMEYER, MD, RONALD A. STINE, MD, CARL V. LEIER, MD, and STEPHEN F. SCHAAL, MD

To examine the electrophysiologic determinants of provoked atrial flutter (AF) in patients with mitral valve prolapse (MVP), studies were performed in 4 groups of patients: group 1 (n = 5), patients with MVP and AF; group 2 (n = 6), patients without MVP but with AF; group 3 (n = 6), patients with MVP but without AF; and group 4 (n = 5), patients without MVP and without AF. P-wave duration, intraatrial conduction, interatrial conduction and effective refractory periods for both the high right atrium and the low right atrium were longer in group 2 than in group 1. The effective refractory period of the low right atrium was longer in group 3 than in group 1. The interatrial conduction interval was longer in group 2 than in group 4. Thus, in patients without MVP, atrial conduction delay is the predominant determinant of AF, whereas differences in right atrial refractoriness appear to be most important to the provocation of AF in the patient with MVP. These differences in atrial refractoriness may be a result of abnormal autonomic influences in patients with MVP. **(Am J Cardiol 1985;56:602–604)**

Atrial flutter (AF) is a relatively common supraventricular arrhythmia generally associated with atrial enlargement[1] or atrial conduction disease.[2,3] Patients with mitral valve prolapse (MVP) in whom AF develops frequently do not have atrial enlargement. The role of atrial conduction and refractory period abnormalities in the development of AF in such patients is not known. To further delineate the electrophysiologic substrates of AF, the development of sustained AF to programmed atrial stimulation was compared in patients with and without MVP and no evidence of atrial enlargement.

Methods

Eighteen patients and 4 normal volunteers (16 women, 6 men), mean age 35 years (range 17 to 61), underwent electrophysiologic study for evaluation of suspected dysrhythmia or drug testing. All patients had palpitations, tachycardia, syncope or chest pain not typical for angina pectoris (Table I). The patients selected were those studied in chronologic order in whom atrial catheter positions were accurately known and AF was either readily reproduced in sustained fashion or was not inducible. The normal volunteers underwent electrophysiologic study related to a drug protocol. Electrocardiographic abnormalities were limited to ventricular premature complexes and nonspecific ST- and T-wave changes. Of the 24 subjects, in 11 MVP was diagnosed by classic auscultatory findings[4] and echocardiography.[5] In 11 patients MVP was excluded in a similar manner. Other than MVP, evidence of heart disease was absent. No patient had evidence of cardiomegaly or atrial enlargement by chest radiography and echocardiography. The echocardiographic criteria used for left atrial enlargement were those of Feigenbaum.[6]

For statistical analysis of the electrophysiologic data, the patients were classified into 4 subgroups based on the presence or absence of MVP and the presence or absence of AF. Group 1 consisted of 5 patients with MVP and provoked AF; group 2 consisted of 6 patients without MVP but with provoked AF; group 3 consisted of 6 patients with MVP but without AF; and group 4 consisted of 5 patients without MVP and without provokable AF. Two of 5 patients with MVP had spontaneous AF and 3 of 6 patients without MVP showed spontaneous AF or flutter-fibrillation (Table I). All groups were statistically similar in mean age.

Comparisons of electrophysiologic measurements were determined for group 1 vs groups 2, 3 and 4; group 2 vs group 4; and group 3 vs group 4.

All studies were performed in the postabsorptive, nonsedated state. Patients taking cardioactive drugs had medications discontinued at least 24 hours before the procedure. Beta-blocking drugs were discontinued at least 72 hours before the study. An esophageal bipolar catheter was positioned fluoroscopically at the level of the midleft atrium. A 6-pole catheter was inserted percutaneously and positioned for recording the His bundle potential. Bipolar or quadripolar catheters were inserted into the high and low right atrium. The high right atrial catheter was positioned anterolaterally near the superior vena cava and the low right atrial catheter in the low lateral right atrium near the inferior vena cava. Atrial pacing was accomplished using a programmed digital stimulator that delivered square-wave impulses at 1½ times the diastolic threshold and 2 ms in duration. Intracardiac electrograms were filtered at 40 to 500 Hz and recorded on an Electronics for Medicine recorder at paper speeds of 50 or 100 mm/s. Simultaneously, surface electrocardiographic leads I, aVF and V_1 were recorded.

Conduction intervals: P-wave duration was determined by measuring the onset to termination of the longest P wave

* Group 1 vs 2 $p < 0.05$; † Group 1 vs 3 $p < 0.05$; ‡ Group 2 vs 4 $p < 0.05$; § Group 1 vs 4 $p < 0.05$.
AF = atrial flutter; ASD = atrial septal defect; ERP = effective refractory period; HR = high right atrium; L = left atrium; LH = lightheaded; LR = low right atrium; Palps = palpitations; PWP = P-wave duration; SD = standard deviation; S/P = status post; SVT = supraventricular tachycardia; Tach = tachycardia.

in electrocardiographic leads I, aVF or V_1. Right intraatrial conduction time was measured as the interval from high right atrial to low right atrial depolarization. The interatrial conduction time was the interval from the high right atrial to left atrial depolarization. The atrioventricular node and His-Purkinje conduction times were determined by measuring the low right atrium to His bundle and His bundle to ventricular depolarization intervals, respectively. The flutter cycle length was defined as the interval between 2 consecutive AF waves; the length of the flutter wave was the interval from beginning to end of the longest flutter depolarization in the high right, low right or left atrial recording.

Arrhythmia provocation and effective refractory periods: Arrhythmia provocation was performed by the extrastimulus technique applied to the high right and low right atria. Six to 8 atrial paced beats, A_1, at a rate of 100 beats/min, were followed by a premature stimulus, A_2. The A_1-A_2 interval was progressively shortened at 10-ms intervals until a sustained tachyarrhythmia was produced or A_2 no longer resulted in a subsequent atrial depolarization. This point was designated the effective refractory period. If pacing with a single premature stimulus did not result in a sustained tachyarrhythmia, A_2 was advanced 10 ms beyond the atrial effective refractory period and a second premature stimulus, A_3, was introduced at progressively premature intervals until a sustained tachyarrhythmia was produced or A_3 was found refractory. Sustained AF was defined as a regular atrial tachycardia at a rate of 250 to 350 beats/min lasting longer than 30 seconds. The arrhythmia was defined as absent if 1 or no repetitive responses developed.

Statistical methods: Measurements are presented as mean ± standard deviation. Comparisons between groups were performed using analysis of variance for a 2-way layout and the Student t test for unpaired data. A $p < 0.05$ was designated as statistically significant.

Results

Five patients with MVP and 6 without had sustained AF in response to programmed electrical stimulation. In patients in whom AF developed, the flutter cycle length and length of flutter wave were not different.

Group 1 (MVP, AV) versus group 2 (no MVP, AF): AH and HV intervals were not significantly different beween the 2 groups. However, when compared with group 1 patients, group 2 patients had longer P-wave duration, longer intraatrial and interatrial conduction intervals, and longer effective refractory periods for both high and low right atria (Table I).

Group 1 (MVP, AF) versus group 3 (MVP, no AF): Group 3 differed from group 1 only by the presence of

a longer effective refractory period of the low right atrium (Table I).

Group 1 (MVP, AF) versus group 4 (no MVP, no AF): Group 1 patients were similar in all measurements to group 4 patients except for a shorter effective refractory period of the low right atrium (Table I).

Group 2 (no MVP, AF) versus group 4 (no MVP, no AF): Interatrial conduction was longer in group 2 than in group 4 patients. All other measurements were not different (Table I).

Group 3 (MVP, no AF) versus group 4 (no MVP, no AF): No significant differences were found between the 2 groups for any of the electrophysiologic measurements.

Discussion

In several previous studies the electrophysiologic factors predisposing to the development of AF have been examined. Leier et al[2] showed that AF was associated with prolonged atrial conduction and an increased P-wave duration. Similarly, Watson and Josephson[3] found atrial conduction defects in 36 of 41 patients with sustained AF. Confirming these findings, our comparison of patients without MVP who had sustained AF vs those who did not have AF showed again that prolonged arial conduction was a marker or prerequisite for development of AF. In contrast, patients with MVP with provokable sustained AF did not show evidence of atrial conduction disease. In fact, compared with the group of patients without MVP who had AF, the MVP-AF group showed a distinct lack of atrial conduction and refractory period prolongation, displaying significantly shorter intraatrial and interatrial conduction times, shorter P-wave durations and shorter atrial effective refractory periods.

The patients without MVP who had AF had greater atrial conduction and refractory period prolongation than the patients with MVP who had flutter when compared with normal subjects. Although the MVP patient with provokable AF was electrophysiologically markedly different from the patient without MVP with AF, the MVP-AF patient different from the MVP patient without provokable AF only by the presence of a shortened low right atrial effective refractory period.

These findings suggest that different mechanisms are responsible for the production of AF in these 2 groups. The patients without MVP appear to have AF as a function of prolonged atrial conduction. Because patients with atrial enlargement were excluded and all groups were similar in age, the likely anatomic substrate is diffuse atrial fibrosis in this group.[7] On the other hand, the shorter low right atrial refractory period displayed by the MVP group who had AF suggests an inhomogeneity of refractory periods, especially since the high right atrial refractory periods were not different. However, multiple sites were not tested; this is required to document the increased temporal dispersion of refractoriness responsible for atrial reentry tachycardia.[8] The difference in atrial refractoriness present in the MVP patients with AF may be secondary to varying degrees of autonomic influence on the right atrial tissue. Gaffney et al[9] showed that MVP patients have an attenuated vagal response to the diving reflex. Prystowsky et al[10] showed that vagal stimulation shortened the effective refractory period of the human right atrium while producing shortening of the midright atrium in 1 patient. These observations may help to explain the disparities of atrial refractoriness noted in our patients. In addition, abnormalities in catecholamine metabolism in MVP patients have been previously reported.[11] These abnormalities alone or in combination with an abnormal vagal response could produce the changes in atrial refractoriness responsible for AF in patients with MVP.

The clinical significance of AF induced by means of premature stimulation in the laboratory is not totally clear. Comparing responses of patients with to without documented spontaneous AF or atrial fibrillation to single atrial extrastimuli, Engel et al[12] found vulnerability to flutter/fibrillation in 75% of those previously documented to have flutter/fibrillation and 36% of patients who were symptomatic (likely owing to dysrhythmias) but had not had atrial flutter/fibrillation during a recent 24-hour period of monitoring. This study did not mention atrial size and other descriptors of potential atrial abnormalities in either group of patients. Thus, although the group with documented atrial flutter/fibrillation would be the one more likely to have provokable flutter/fibrillation, both groups would be expected to have provokable arrhythmias. Studies performed on normal volunteers[13] have shown practically no tendency to flutter/fibrillation in response to single or double atrial extrastimuli. This finding, coupled with the documented contribution of atrial conduction disease to the development of AF, tend to make the disparate responses of the MVP patients, which appear potentially related to the different atrial effective refractory periods, all the more enlightening.

Transderm-Nitro®

(nitroglycerin)
Transdermal Therapeutic System

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE
This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.
In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.
Transdermal nitroglycerin systems should be removed before attempting defibrillation or cardioversion because of the potential for altered electrical conductivity which may enhance the possibility of arcing, a phenomenon associated with the use of defibrillators.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.
Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.
Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.
The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response. The Transderm-Nitro 2.5 system is useful principally for decreasing the dosage gradually, though it may provide adequate therapy for some patients when used alone.
The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.
Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

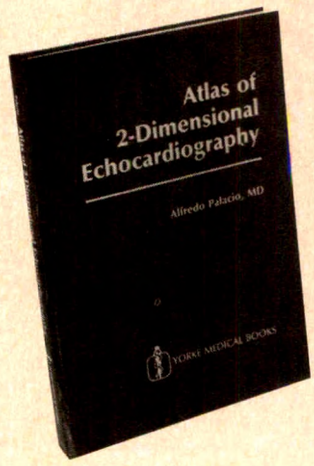
A "how-to-do-it" text/atlas presen broadest range of normal and ab 2-dimensional echocardiogra



Atlas of 2-Dimensiona Echocardiogr

by Alfredo Palacio, MD
Director of National Institute of Cardiology,
Foreword by David H. Spodick, M
Professor of Medicine, University of Massachi School; Director, Division of Cardiology, St. Worcester, Massachusetts
ISBN 0-914316-35,4, 198pp., illus.
8¼ x 12, March '83, $69.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS of 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a large 8½ x 12 format 251 black and white half tones, 152 line drawings and 6 charts which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

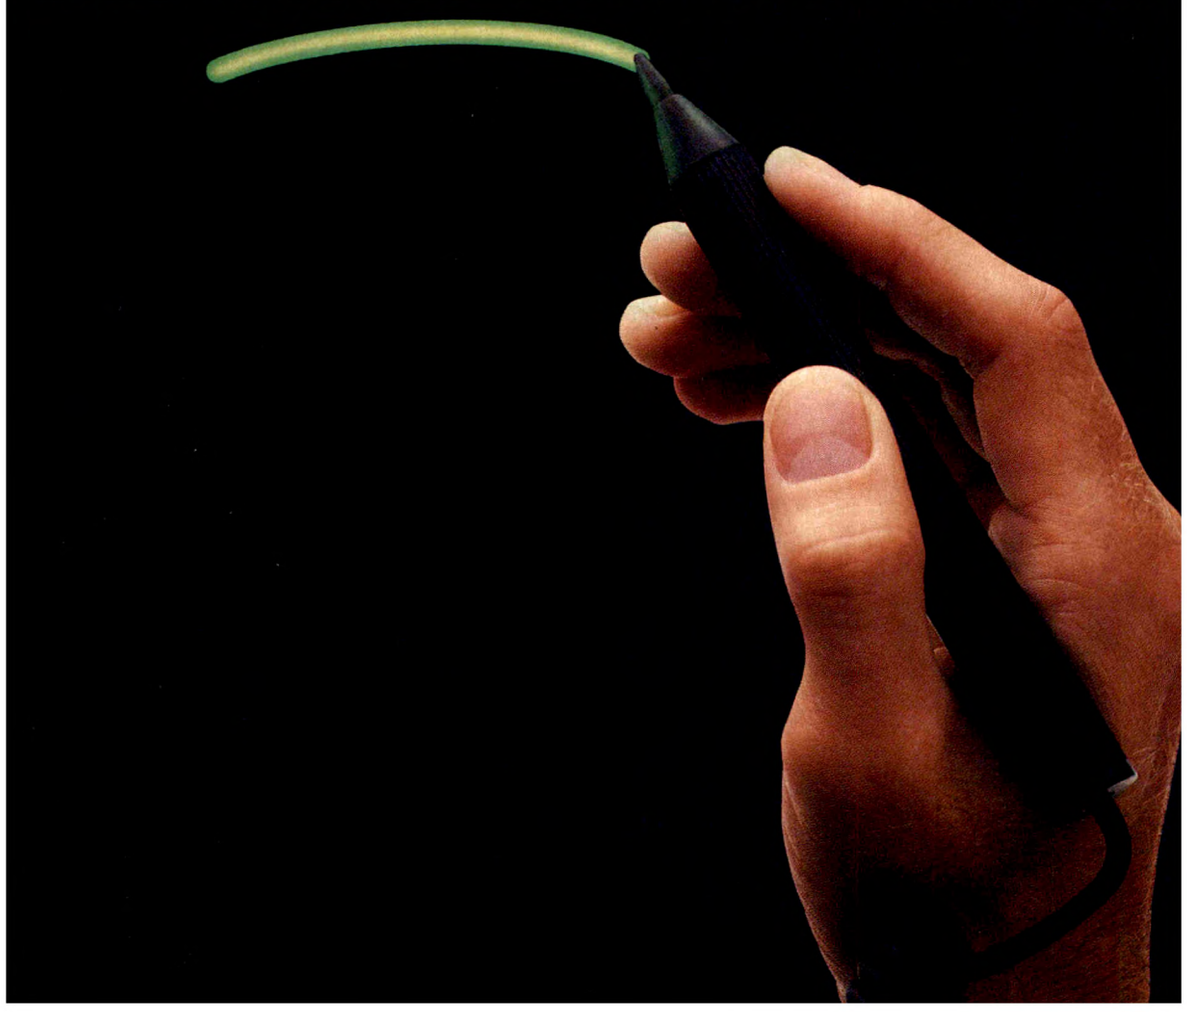
DEVELOPING THE WORLD'S MOST ADVANCED DDD PACING SYSTEM IS A GREAT IDEA.

BUT IT SHOULD ALSO BE SIMPLE TO USE.



INTERMEDICS

COSMOS®

THE EASE OF CONTROL COSMOS OFFERS YOU IS AS UNIQUE AS THE HEART IT SERVES.

The Rx2000 Programmer Wand puts telemetry inquiries and programming functions at your fingertips.

Everything you need is at your fingertips.

From the moment you turn on the Rx2000 programmer, you'll find that everything has been done to make your use of COSMOS simple, fast, effective and safe.

Pick up the light pen and press it to the screen. A full display comes to life telling you every facet of COSMOS, including that the implanted pacer is a COSMOS. Programming the parameters that suit your patient's condition is simply a matter of pressing the light pen to the function you wish to change, for example Refractory Period, and turning the knob on the Rx2000 until the desired value appears next to the title. Programming increments are small, so you can easily set the value that's

The Rx2000 Programmer leads you through the COSMOS programming sequence step-by-step.

right for your patient. If changing one value affects any others, the Rx2000 automatically tells you about it and what to do. And automatic control of PMT and crosstalk inhibition assures your patient's safety.

Need an explanation?

Just press the EXPLAIN key and a full, plain-English text appears on the screen to describe the programming procedure.

Adjusting any COSMOS *parameter is as simple as pointing a light pen and turning a knob.*

Now, with all of the parameters you wish set in place, just press the PROGRAM DISPLAY button. You're done.

If you want to know what the patient's COSMOS has stored in its remarkable memory, select DIAGNOSTIC DATA and it's all on the screen. Press a button and it's printed out for your patient's file.

It's all that simple.

Now you're beginning to understand why leading physicians who have already prescribed COSMOS are making it their choice for DDD pacing.

Getting to know COSMOS is even easier.

Intermedics has a complete range of educational video cassettes that cover everything from implant techniques to advanced DDD pacing concepts. Just ask your Intermedics representative to show you the DDD pacing system as unique as the heart it serves.

COSMOS *shown with* CARDIFIX™ 479-01 *leads.*

Intermedics Inc.®

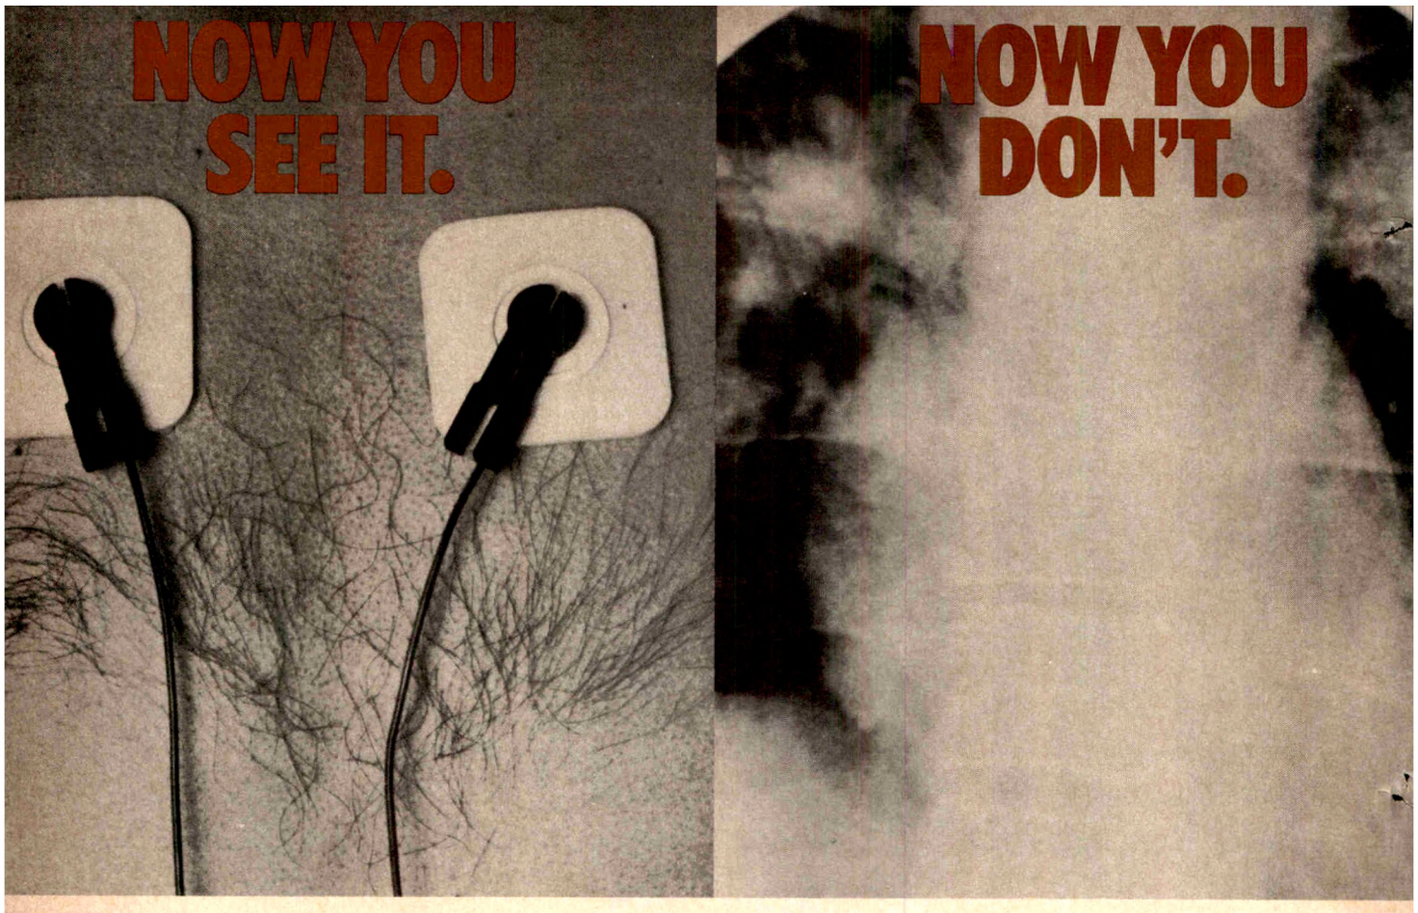
In Texas: 1-800-392-3726
Telex: 4620491ITM or 792713SLFPRT

Intended Uses: All intermedics implantable pulse generators are intended for use in long-term cardiac pacing therapy. The applications for long-term cardiac pacing are many and varied and are discussed as they apply to the particular pulse generator in the Physician's Manual accompanying the device along with Contraindications, Possible Complications and Precautions.

The choice of pacing modes and/or programmable features that best meet the therapeutic requirements of the individual patient is at the discretion of the prescribing physician.

For further information, see the Physician's Manual packaged with the pulse generator, or contact your Intermedics Sales Representative or Intermedics directly.



QUINTON'S CLEAR-LEAD® IS THE CLEAR CHOICE FOR ECG MONITORING.

Don't let ECG leadwires get in the way of your nuclear and imaging studies. Get the whole picture with Quinton's new CLEAR-LEAD radiotransparent leadwires.

Use them with our line of radiolucent electrodes. Together, they're the clear choice for the cath lab. The nuclear medicine department. The critical care unit. Wherever you need ECG *and* a clear picture.

The quality choice.

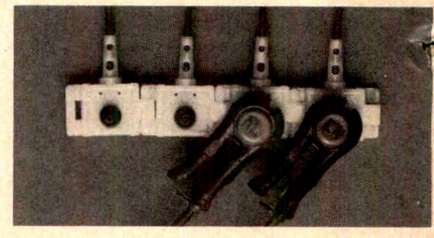
With Quinton's new CLEAR-LEAD technology, the leadwires and electrodes don't interfere with your picture so you can position the electrodes where they'll get the most accurate signal possible.

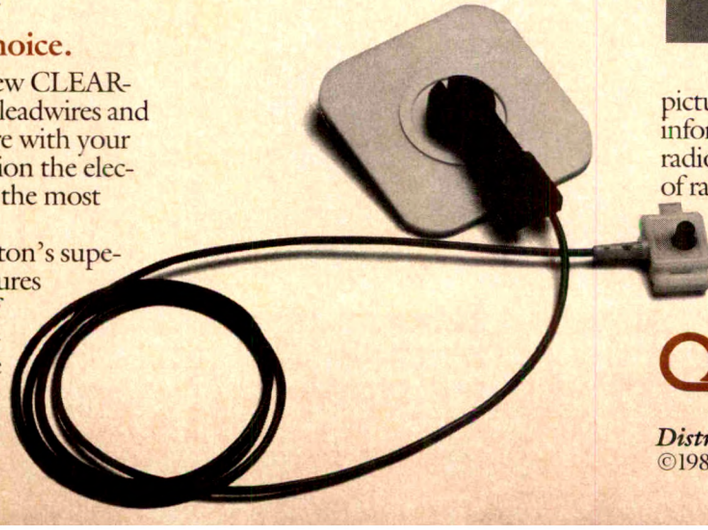
And because Quinton's superior electrode design insures a continuous column of gel, you'll get a dependable signal. With a more stable baseline. And less motion artifact. Even if the patient's moving.

The practical choice.

Unlike other radiotransparent leadwires, Quinton's new CLEAR-LEAD leadwire sets are reusable. You'll get up to 100 uses out of each wire—making them the practical choice when it comes to budgeting.

What's more, CLEAR-LEAD is designed to work with virtually any ECG equipment in use today. Its convenient junction box serves as a link between the machine's own leadwires and the CLEAR-LEAD set.





Isn't it time you got the whole picture? The choice is clear. For more information about CLEAR-LEAD radiotransparent leadwires or our line of radiolucent electrodes, call or write Quinton Instrument Company, 2121 Terry Avenue, Seattle, WA 98121, 1-800-431-1114. Telex 3794094.

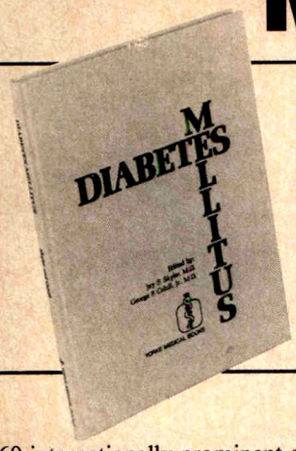
DIABETES MELLITUS



From the publishers of the American Journal of Medicine

Jay S. Skyler, M.D.,
University of Miami School of Medicine

George F. Cahill, Jr., M.D.,
Harvard Medical School and Howard Hughes Medical Institute

60 internationally prominent contributors provide in 26 papers a comprehensive overview of the current thinking on the causes, mechanisms, treatment and complications of diabetes.

Featured topics include:

- ☐ The causes of diabetic inheritance
- ☐ Immune factors of diabetes
- ☐ Mechanisms of diabetes (The culmination of 50 years of research)
- ☐ Autoimmunity
- ☐ New understandings in the mechanisms of insulin dependent and non-dependent diabetes mellitus
- ☐ New developments in the treatment of diabetes
- ☐ Methods of monitoring blood glucose and the use of glycosylated hemoglobin
- ☐ Pharmacology of oral hypoglycemics
- ☐ Use of insulin infusion devices
- ☐ Human insulin produced by recombinant DNA technology

If it is important to you in your practice to stay up-to-date on the latest developments in Diabetes Mellitus and you need a quick reference on the topic, then this is the book for you.

DIABETES MELLITUS

NITROSTAT®
(nitroglycerin tablets, USP)

Before prescribing, please see full prescribing information. A Brief Summary follows:

INDICATIONS
Nitroglycerin is indicated for the prophylaxis, treatment and management of patients with angina pectoris.

CONTRAINDICATIONS
Sublingual nitroglycerin therapy is contraindicated in patients with early myocardial infarction, severe anemia, increased intracranial pressure, and those with a known hypersensitivity to nitroglycerin.

PRECAUTIONS
Only the smallest dose required for effective relief of the acute anginal attack should be used. Excessive use may lead to the development of tolerance. Nitrostat tablets are intended for sublingual or buccal administration and should not be swallowed. The drug should be discontinued if blurring of vision or drying of the mouth occurs. Excessive dosage of nitroglycerin may produce severe headaches.

ADVERSE REACTIONS
Transient headache may occur immediately after use. Vertigo, weakness, palpitation, and other manifestations of postural hypotension may develop occasionally, particularly in erect, immobile patients. Syncope due to nitrate vasodilation has been reported. Alcohol may accentuate the cerebral ischemia symptoms.

METHOD OF ADMINISTRATION
One tablet should be dissolved under the tongue or in the buccal pouch at the first sign of an acute anginal attack. The dose may be repeated approximately every five minutes until relief is obtained. Nitrostat may be used prophylactically five to ten minutes prior to engaging in activities which might precipitate an acute attack.

HOW SUPPLIED
Nitrostat is supplied in four strengths in bottles containing 100 tablets each, with color-coded labels, and in color-coded Patient Convenience Packages of four bottles of 25 tablets each.

0.15 mg (1/400 grain):
N 0071-0568-24—Bottle of 100 tablets;
N 0071-0568-13—Convenience Package.

0.3 mg (1/200 grain):
N 0071-0569-24—Bottle of 100 tablets;
N 0071-0569-13—Convenience Package.

0.4 mg (1/150 grain):
N 0071-0570-24—Bottle of 100 tablets;
N 0071-0570-13—Convenience Package.

0.6 mg (1/100 grain):
N 0071-0571-24—Bottle of 100 tablets;
N 0071-0571-13—Convenience Package.

NATURE
HAS A WAY
OF PROTECTING
ITS OWN.

So does NITROSTAT®
(nitroglycerin tablets, USP)

Just by the way it's made, NITROSTAT, too, has built-in protection—protection against loss of nitroglycerin. In fact, NITROSTAT is more stable than conventional nitroglycerin tablets under all conditions of temperature and humidity tested.

But that's not all. Average assay still shows better than 100% of label claim for at least 60 months after manufacture of NITROSTAT. Because of this stability NITROSTAT has a five-year expiration date.*

What's more, only NITROSTAT Tablets are available in convenient packages of 4 x 25 tablets. So emergency angina relief can be ready when needed in four different locations. "Because of its rapid action, long-established efficacy, and low cost, nitroglycerin is the most useful drug among the organic nitrates that can be given sublingually."[1]

NITROSTAT...useful alone or as concomitant therapy with long-acting nitrates or propranolol.

*Five-year expiration date when stored at recommended storage conditions in an unopened bottle. Data on file, Medical Affairs Dept. Parke-Davis.

Prognostic Significance of Exercise-Induced Left Ventricular Dysfunction in Chronic Aortic Regurgitation

DAVID S. GEE, MD, JACK E. JUNI, MD, JOHN T. SANTINGA, MD, and ANDREW J. BUDA, MD

Twenty-three patients with hemodynamically significant aortic regurgitation (AR) underwent gated equilibrium radionuclide angiography to assess rest and exercise left ventricular ejection fraction (LVEF) before and after aortic valve replacement. Preoperatively, LVEF decreased from 54 ± 3% at rest to 45 ± 3% during exercise ($p < 0.001$). Two patients died at operation. Postoperatively, after 5.7 ± 1.6 months, LVEF was 62 ± 5% at rest and 60 ± 4% during exercise (difference not significant). Exercise LVEF improved significantly postoperatively ($p < 0.01$). The patients were followed for a mean of 30 months (range 1 to 56), after valve replacement and during this period, 13 patients were in functional class I, 5 patients were in class II and 2 patients were in class III. One late death occurred and was unrelated to myocardial failure. Thus, in most patients with AR, exercise LVEF improves after aortic valve replacement. A preoperative decrease in LVEF during exercise in patients with significant AR does not predict a poor postoperative outcome. (Am J Cardiol 1985;56:605–609)

The timing of valve replacement in chronic aortic regurgitation (AR) is controversial. Several hypotheses have been proposed concerning the development of irreversible myocardial dysfunction in chronic AR and the identification of patients at high risk for surgical intervention.[1–11] Among these is the suggestion that a preoperative decrease in radionuclide left ventricular (LV) ejection fraction (EF) may predict a high-risk group of patients who may have subsequent deterioration in myocardial function after aortic valve replacement.[5–7] We evaluated the rest and exercise LVEF in patients with chronic AR before and after aortic valve replacement and assessed the prognostic significance of a preoperative exercise-induced decrease in LVEF.

Methods

Sixty-two patients were identified who had undergone aortic valve replacement between 1978 and 1982. Twenty-three of these patients met the criteria for inclusion in our study: (1) chronic AR with no other significant valvular disease, (2) preoperative rest and exercise radionuclide angiography performed within 4 months of valvular replacement, (3) cold potassium cardioplegia for myocardial preservation during valve replacement, and (4) no history of endocarditis or intravenous drug abuse.

Equilibrium gated radionuclide angiography was performed with in vivo labeling of red blood cells.[12,13] Patients performed symptom-limited, graded, supine exercise on a bicycle ergometer. Rest and peak exercise LVEF were calculated using a commercial semiautomated, edge-detection algorithm to determine background-corrected LV counts on a frame-by-frame basis. All preoperative radionuclide studies were done within 4 months of surgery and all postoperative studies were done no earlier than 6 months after valve replacement. Wall motion was assessed by consensus of 2 observers at rest and during peak exercise.

All patients underwent right- and left-sided cardiac catheterization preoperatively. In addition to supravalvular and biplane LV angiography, coronary arteriography was performed in all patients older than 40 years. AR was graded on a 4+ scale using standard criteria.[14]

All patients were interviewed concerning their current New York Heart Association functional status. The patient's functional status and medications being used were reviewed at that time. In addition, follow-up on any cardiac-related complications was determined.

Results are reported as mean ± standard error of the mean. Standard statistical techniques, including Pearson's correlation coefficient and t tests, were used.

Results

The results are tabulated in Table I. The study group included 15 men and 8 women, mean age 55 years (range 26 to 72). The mean known duration of AR was 29 months (range 0 to 144). The cause of AR was rheumatic heart disease in 13 patients, and bicuspid aortic valve with a perforated right cusp in 1 patient; the cause was unknown in 9 patients. Four patients had previous hospital admissions for congestive heart failure. The predominant symptoms were shortness of breath with exertion in 14 patients, chest pain in 7 patients, and syncope in 3 patients.

Preoperative cardiac catheterization data: All patients had at least grade 3/4 AR by aortic root cineangiography, with a mean severity score of 3.8. The mean cardiac output was 5.8 ± 1.6 liters/min and LV

AR = aortic regurgitation; BB = β-blocking drug; CAD = coronary artery disease; D = diuretic; Dig = digitalis; LVEF = left ventricular ejection fraction; N/A = not available; NYHA = New York Heart Association; V = vasodilator.

end-diastolic pressure was 16 ± 2 mm Hg. Six patients had 70% or greater luminal stenosis of 1 or more major coronary arteries. Two patients each had 1-, 2- and 3-vessel disease.

Preoperative radionuclide angiographic data: Preoperatively, LVEF at rest was 54 ± 3%, and it decreased significantly with exercise to 45 ± 3% ($p < 0.001$) (Fig. 1). Only 2 patients, both in New York Heart Association functional class II, had an increase in LVEF, of 2% and 4%, respectively, with exercise. Analysis of LV wall motion showed that wall motion worsened with exercise in 12 patients, did not change in 10 patients and improved in 1 patient.

Surgical results: There was only 1 perioperative cardiac-related death: a 60-year-old man (patient 17) with 3-vessel coronary disease died of intractable ventricular tachyarrhythmias after an intraoperative myocardial infarct. Another patient, a 66-year-old man (patient 16), died of respiratory failure caused by bilateral phrenic nerve paralysis. Twenty-one patients had no significant perioperative complications.

Seven patients received Björk-Shiley prosthetic valves, 5 received Starr-Edwards valves and 11 received porcine valves. All patients with mechanical valves received anticoagulation therapy before discharge from the hospital. Of the 6 patients with coronary artery disease, 4 underwent concurrent coronary artery bypass operation.

Postoperative radionuclide angiographic data: In 13 of the 23 patients, postoperative rest and exercise radionuclide angiographic studies were performed. The studies were performed no earlier than 6 months after aortic valve replacement and at a mean of 9.2 months. Compared with preoperative values, there was no postoperative change in maximal rate-pressure product achieved (217 ± 10 vs 202 ± 14 mm Hg/min × 10^2, difference not significant [NS]). The postoperative LVEF at rest in these 13 patients was 59 ± 2%; it increased to 60 ± 4% during exercise (NS) (Fig. 2). Pre- and postoperative LVEF at rest in these 13 patients was not significantly different, 56 ± 4% vs 62 ± 5% ($p = 0.19$). However, there was a significant increase postoperatively in exercise LVEF, from 48 ± 4% to 60 ± 4% ($p < 0.01$) (Fig. 3). A comparison of pre- and postoperative wall motion abnormalities showed that there was improvement in 7 patients, no change in 3 patients, worsening in 1 patient, and inadequate technique precluded comparison in 2 patients. Exclusion of patients with significant coronary artery disease or coronary artery bypass grafts did not influence any of the postoperative results.

Clinical follow-up: The mean patient follow-up period of the 21 surviving patients was 30 months (range 1 to 56). The change in New York Heart Association functional class is shown in Figure 4.

There was only 1 late death, a 59-year-old man (patient 18) with Marfan syndrome who died after aortic root replacement 6 months after aortic valve replacement. Two patients with mechanical valves had cerebrovascular accidents despite therapeutic anticoagulation.

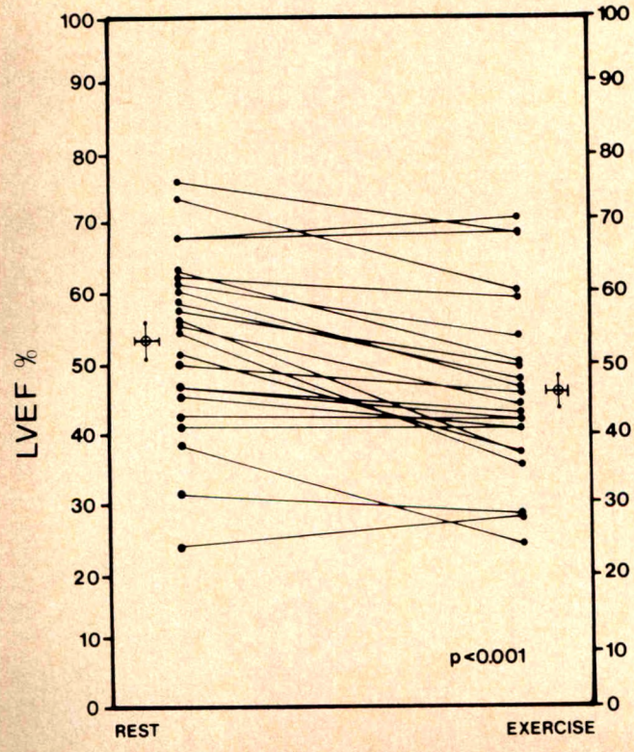

FIGURE 1. Preoperative change in left ventricular ejection fraction (LVEF) with exercise.

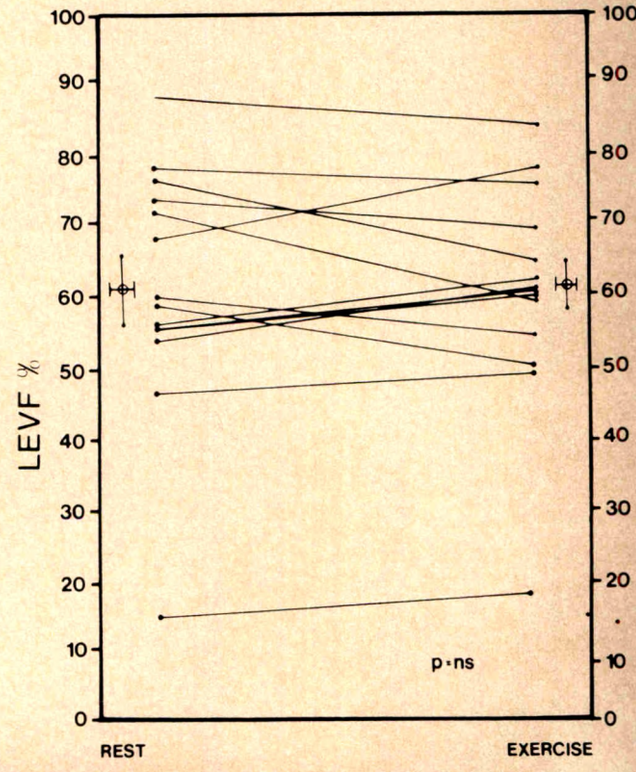

FIGURE 2. Postoperative change in left ventricular ejection fraction (LVEF) with exercise. NS = not significant.

Discussion

A major concern in chronic AR has been the development of irreversible myocardial dysfunction, which results in late death from congestive heart failure despite technically successful valve replacement. For example, 78% of late postoperative deaths from 1972 to 1978 at the National Institutes of Health (NIH)[9] were related to chronic congestive heart failure. As a result, several prognostic indicators related to LV dimensions and systolic function have been proposed to aid in the appropriate timing of surgery and in the identification of the high-risk patient who may respond poorly to valve replacement and have late congestive heart failure.[1–11]

In our study, all asymptomatic patients had a decrease in LVEF with exercise. Previous studies[5–7] have shown that most asymptomatic and symptomatic patients with chronic AR have an abnormal ejection fraction response during maximal supine exercise. It has been hypothesized that the decrease in radionuclide LVEF with exercise may represent an intermediate point between normal function and LV dysfunction at rest.[5] It has been further suggested that an abnormal exercise ejection fraction response may allow selection of patients for operation after ventricular function has begun to deteriorate, but before myocardial damage has progressed to the point at which postoperative prognosis is poor.[6] However, exercise is a complex intervention that induces changes in preload, afterload and contractility, which may affect ejection fraction variably in chronic AR.[15] Thus, it is difficult or impossible to differentiate a change in EF in chronic AR because of marked loading perturbations from that resulting from myocardial degenerative changes.

The primary finding in our study was that despite a decrease in preoperative exercise LVEF, patients with chronic AR had an excellent postoperative course. After a mean follow-up of 30 months, no patient who survived surgery had died or had congestive heart failure. These data suggest that exercise-induced LV dysfunction is compatible with a good long-term postoperative result and does not necessarily predict a poor postoperative course.

There is increasing evidence that exercise-induced LV dysfunction in symptomatic patients is often reversible after surgery.[7,16,17] In a consecutive series from 1976 to 1980, 93% of patients who underwent surgery at the NIH had an improvement in postoperative exercise LVEF.[7] In our series, there was a postoperative improvement in 64% of our patients. Unlike the NIH series, we did not find a significant improvement in the rest LVEF, probably because our patients had generally better LV function at rest than those of the NIH series. However, the long-term prognosis of patients who have an abnormal exercise LVEF before surgery has not been previously reported.

Our survival results after aortic valve replacement appear better than those previously reported.[7,18–20] This apparent improvement in survival has several possible explanations. First, all of our patients had cold potassium cardioplegia at the time of aortic valve replacement, which may have limited perioperative myocardial damage. Many data support the concept that advances in myocardial preservation techniques during surgery have improved postoperative survival.[3,21,22] Second,

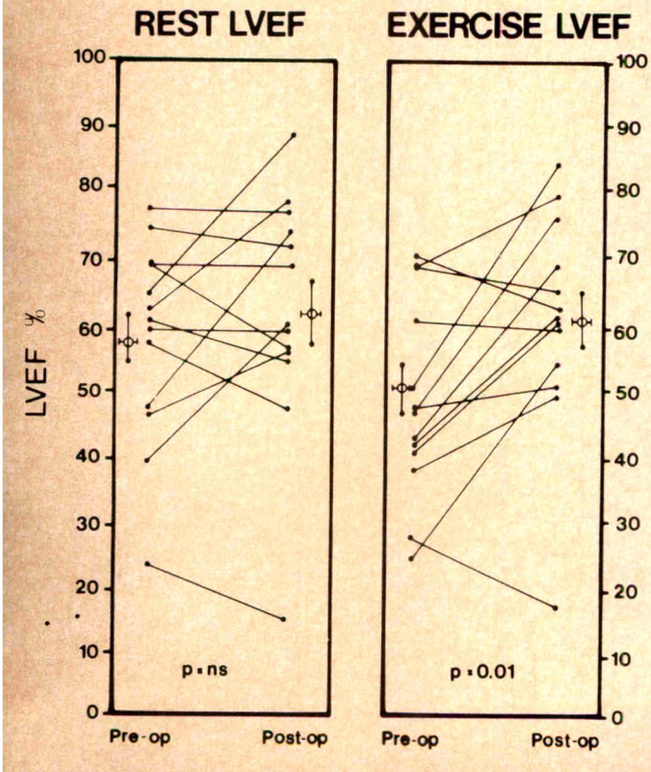

FIGURE 3. Comparison of preoperative and postoperative rest and exercise left ventricular ejection fraction (LVEF).

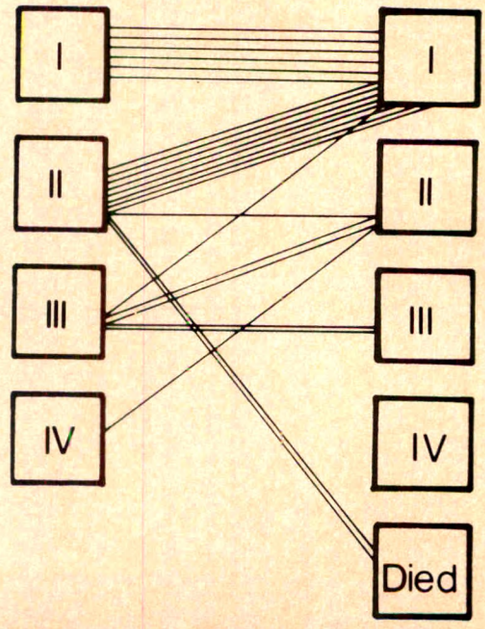

FIGURE 4. Changes in New York Heart Association functional class after valve replacement.

most of our patients with coronary artery disease underwent coronary bypass grafting. Myocardial revascularization may have improved long-term survival, although the benefits of coronary bypass grafting in patients with chronic AR remains controversial.[23] Third, exercise radionuclide abnormalities may have influenced the selection of patients for earlier operation; 6 of 23 patients were asymptomatic and 11 were only mildly symptomatic. Recent data from the NIH[17] suggest that there is a relation between the duration that LV dysfunction has existed and the likelihood that this dysfunction is reversible. Patients with earlier development of LV dysfunction are more likely to demonstrate normalization of LV function postoperatively than are patients whose LV dysfunction has been present longer than 1 year. None of our patients had serial radionuclide studies; thus, this relation may have influenced our survival results.

The precise role of the exercise EF response in patients with chronic AR remains to be determined. There are limited data on serial studies of rest and exercise LVEF in asymptomatic or symptomatic patients with chronic AR. Thus, the prognostic significance of a change in serial rest and exercise LVEF is uncertain. However, our data suggest that an exercised-induced abnormality in LVEF is common in patients being considered for aortic valve replacement and does not in itself predict a poor surgical result.

Clinical and Echocardiographic Observations in Pulmonary Valve Endocarditis

ANNE-CLAUDE CREMIEUX, MD, SERGE WITCHITZ, MD, MARIE-CHRISTINE MALERGUE, MD, MICHEL WOLFF, MD, DANIEL VITTECOCQ, MD, JEAN-LOUIS VILDE, MD, JACQUES FROTTIER, MD, PIERRE ETIENNE VALERE, MD, CLAUDE GIBERT, MD, and ADRIEN G. SAIMOT, MD

Clinical and echocardiographic data from 12 patients with pulmonary valve endocarditis are described. Seven patients had isolated pulmonary endocarditis and in 5 patients other valves were infected (aortic, tricuspid, mitral or all 3). Two patients were heroin addicts and 4 had underlying heart disease (congenital heart disease in 3 and aortic regurgitation in 1 patient). The organisms involved were *alpha streptococci* in 3 patients (all with underlying heart disease), *Staphylococcus aureus* in 4, *Streptococcus D bovis* in 1 patient and *Candida guillermondii* in 1. M-mode and 2-dimensional echocardiography was performed in 10 patients and revealed vegetations in 8. Pulsed Doppler echocardiography was performed in 6 patients and revealed pulmonary regurgitation in all 6. Seven patients had pulmonary emboli. Four patients underwent surgery. Four patients died, including 1 after cardiac surgery. Five patients, including the patient infected with *Candida guillermondii*, recovered with antibiotic treatment.

(Am J Cardiol 1985;56:610–613)

Pulmonary valve (PV) endocarditis is rare. Only 47 cases have been reported since 1960,[1–29] most of these being 1 or 2 cases of drug addicts or patients with congential heart disease. We report 12 patients with PV endocarditis.

Methods

Twelve cases of PV endocarditis were observed at Claude Bernard and Bichat Hospitals between 1972 and 1984. The diagnosis of PV endocarditis was made on the basis that septicemia was present and the PV was affected. PV involvement was confirmed by anatomic examination (surgery or autopsy), echocardiographic images of vegetations or by recent PV regurgitation diagnose by auscultation or pulsed Doppler echocardiography.

Echocardiography: Ten patients had echocardiographic examinations (M-mode and 2-dimensional [2-D] in 9 patients and M-mode alone in 1 patient). The echocardiographic examination was done either with a phased-array sector scanner (RT 400) with an M-mode type Irex II or with a mechanical sector scanner (ATL Mark 500) with a 3 MHz in-line transducer. PV recording was done in the short-axis view and the transducer was placed on the third or fourth intercostal space in a parasternal view visualizing the pulmonary outflow tract. The valves, the size of the right ventricle and septal motion were systematically examined using the usual methods. Several recordings were made during follow-up.

Diagnosis of vegetations was made when abnormal, shaggy, irregular echoes were seen on or near 1 or 2 pulmonary cusps and the motion of the cusps was not restricted.

Six patients underwent 2-D pulsed Doppler echocardiographic examinations with an ATL Mark 500 mechanical scanner. The sample volume (2 mm) was positioned along an M-mode line simultaneously with the 2-D image. For the PV examination, the sample volume was placed just below the pulmonary cusps in a short-view axis. PV regurgitation was demonstrated when abnormal positive diastolic turbulence was recorded toward the transducer and the pulmonary ejection signal moved away from the transducer.

Results

The clinical and bacteriologic results are summarized in Table I.

Clinical findings: The patients were 3 to 61 years old (mean 34). Eleven patients were men (92%). The patients were separated into 2 groups. Group I included 4 patients with underlying heart disease (congenital in 3). Group II included 8 patients with primitive PV endocarditis (2 heroin addicts, 2 alcoholics and 4 with no predisposing factors).

Seven patients (59%) had isolated PV endocarditis and in 5 patients other valves were infected (aortic in 1 patient, tricuspid in 2 patients, mitral in 1 and all 3 valves in 1).

Fever was present in all cases. A typical PV regurgitation murmur was found in only 3 patients (25%), all in group II. Associated aortic regurgitation masked the pulmonary auscultation in 2 other patients. One patient

had right-sided congestive heart failure and 1 had left-sided heart failure. Seven patients (59%) had septic pulmonary emboli. The other signs of endocarditis were splenomegaly in 5 patients, arthralgia in 2, arthritis in 1 patient, purpura in 1 and proteinuria in 4.

The portal of entry was found in 7 patients (Table I).

Bacteriologic findings: Positive blood cultures were found in 9 cases: coagulase-positive staphylococci in 4 patients, including 1 methicillin-resistant case; *alpha streptococci* in 3; *Streptococcus D bovis* in 1; and *Candida guillermondii* in 1. Negative blood cultures were found in 3 patients who had taken antibiotics before hospitalization.

M-mode, 2-dimensional and pulsed Doppler echocardiography: Echocardiography revealed PV vegetations in 8 of 10 patients. However, for patients 3, 4, 7 and 8, the first echocardiogram, done on days 31, 14, 5 and 10, respectively, of the illness, yielded normal findings, although a typical diastolic murmur had been noted previously in patient 7. In addition, tricuspid valve fluttering was observed in patients 9, 10 and 11, and paradoxical septal motion with right ventricular hypertrophy in patients 9 and 10. Echocardiography did not reveal vegetations in patients 11 or 12. Patient 11 had only an M-mode echocardiogram, which did not visualize the PV. In patient 12 the 2-D echocardiogram was normal, but the M-mode echocardiogram revealed diastolic vibrations, suggesting valve impairment. The M-mode and 2-D echocardiographic results for patient 9 are shown in Figure 1. On day 30, the PV vegetation was visible; 48 hours later, the abnormal echoes had disappeared. This patient had had several episodes of pulmonary emboli. Images of PV vegetation disappeared in patient 2, and remained unchanged in the others.

Six patients had pulsed Doppler echocardiographic examinations. PV regurgitation was diagnosed in all 6. Figure 2 shows the pulsed Doppler echocardiogram from patient 12; a considerable diastolic flow suggestive of pulmonary regurgitation is visible.

Anatomic findings: Anatomic study was possible in 6 patients (2 autopsies and 4 operations). PV vegetations were found in all 6. Vegetations were also found on the right ventricle in patient 2, the tricuspid valve in patients 2 and 11, the mitral valve in patients 6 and 11 and the aortic valve in patients 4 and 11. The anterior pulmonary leaflet was destroyed in patient 1.

Treatment and clinical outcome: The illness lasted from 8 to 90 days (average 45). All patients were first treated with antibiotics 2 to 90 days (average 18) after the onset of illness.

In group I, 3 patients had cardiac surgery: patients 1 and 4 were cured with antibiotics and underwent surgery several months later to correct underlying heart disease; patient 2 had surgery after a 40-day course of antibiotic treatment, to correct heart disease, persistent large vegetations and repeated pulmonary emboli, and she recovered; patient 3 had leukemia and also mycotic endocarditis, which was cured by antibiotic therapy.

In group II only 1 patient (no. 11) had surgery, for left-sided heart failure owing to aortic regurgitation, but

TABLE II Pulmonary Valve Endocarditis: Comparsion of Current Study Group with Published Cases

Category	Our Group (12 Cases)	Published Cases (47 Cases)
Incidence PV IE/Total IE	1.5%	1.7% (Roberts), 2% (Johnson)
Mean age (yr)	34	35
Primitive PV alone	5 (42%)	9 (19%)
Congenital heart disease	25%	51%
Opiate addiction	17%	32%
PR murmur	25%	61%
Pulmonary embolism	59%	61%
Right-sided CHF	8%	12%
Recovery	67%	59%

CHF = congestive heart failure; IE = infective endocarditis; PR = pulmonary regurgitation; PV = pulmonary valve.

he died of cardiac tamponade 14 days later. PV endocarditis was diagnosed at autopsy in patients 5 and 6. Patient 10 died suddenly after 24 days of antibiotic therapy, but autopsy was not possible. Four other patients were successfully treated with antibiotic therapy.

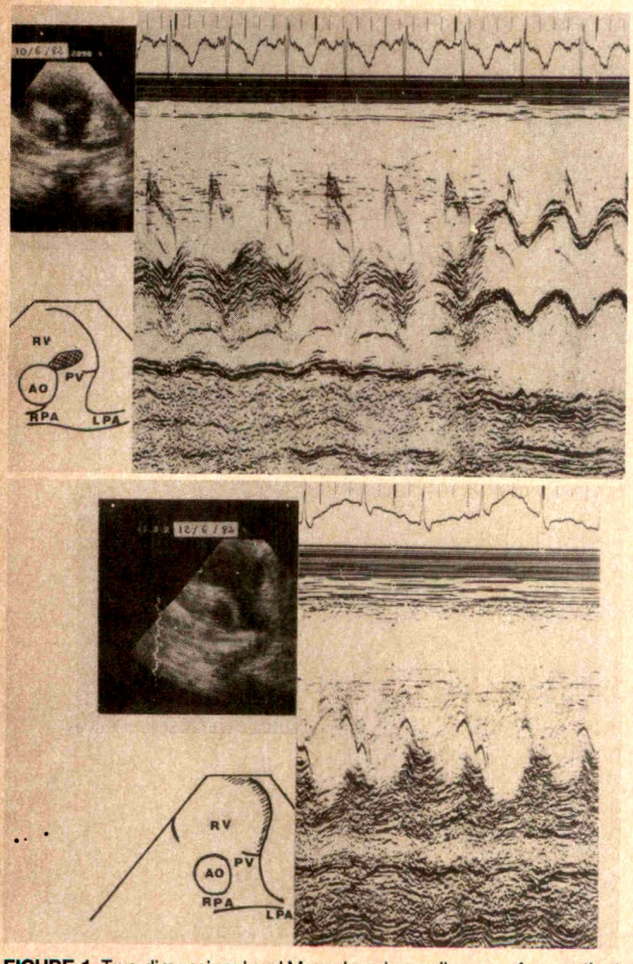

FIGURE 1. Two-dimensional and M-mode echocardiograms from patient 9. **Top,** day 30. A shaggy abnormal echo is present on the posterior pulmonary cusp. **Bottom,** day 32. The vegetation has disappeared. AO = aorta; LPA = left pulmonary artery; PV = pulmonary valve; RPA = right pulmonary artery; RV = right ventricle.

Surgery involved insertion of bioprostheses on the pulmonary and aortic valves for patient 4, resection of the PV in patient 1 and resection of PV vegetations in patients 2 and 11.

Discussion

The PV is the valve the least often involved in infective endocarditis. We found 47 reported cases since 1960 (Table II). However, the frequency of PV endocarditis apparently has increased. In our series, 10 of 12 cases were observed between 1982 and 1984, and the number of reported cases increases regularly. This is probably partly because of better diagnosis. In our study, PV endocarditis accounts for 1.5% of patients admitted for infective endocarditis. Roberts and Buchbinder[21] estimated that PV endocarditis accounts for 1.7% of fatal endocarditis cases; Johnson et al[1] reported that PV endocarditis accounts for 2% of endocarditis in subjects younger than 25 years. In addition, necropsy studies of endocarditis in heroin addicts[2,15,30] show that the PV is involved one-tenth as often as the tricuspid valve. Five of our patients (42%) had PV involvement alone without underlying heart disease. Only 9 patients (19%) so affected have been reported previously.[16–18,22–26] PV endocarditis was more common in patients with congenital heart disease[1–14] and in heroin addicts[2–11,15–20] than in our series (Table II).

When PV endocarditis affected a healthy heart, a virulent organism, often *Staphylococcus*, was usually found. However, when patients with congenital heart disease were affected, the causative organism was often alpha *Streptococcus*. *Gonococcus*, formerly considered to be a frequent organism in PV endocarditis,[31] is now seldom found; 2 cases have been reported since 1960.[25,26] To our knowledge, our patient 11 is the first case of myocotic PV endocarditis.

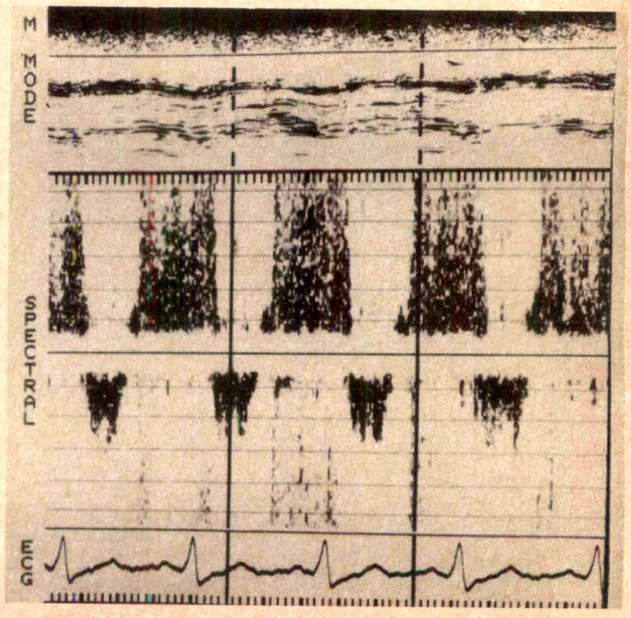

FIGURE 2. Pulsed Doppler echocardiogram from patient 12. Abnormal diastolic turbulence is recorded just below the pulmonary cusps.

More than half of the patients had pulmonary emboli (Table II). Diastolic murmur due to pulmonary regurgitation was not always detected; it may be masked by the murmur because of aortic regurgitation. Right-sided congestive heart failure was found in only 5 patients.[5,7,8,12] In 4 patients this was a result of partial or total obstruction of the PV caused by a large vegetation.

The first echocardiographic diagnosis of PV vegetation was by Kramer et al[20] in 1977. Since then, 16 cases have been reported,[2,13,14,17,18,20,25,26] 10 of which were confirmed by histopathologic study. In 2 of our patients the echocardiographic examination did not detect PV vegetations. Patient 9 did not undergo 2-D echocardiographic examination. Two-dimensional echocardiography is more sensitive than M-mode echocardiography for detecting PV vegetations.[14] PV vegetations were not visualized in patient 10, but valve impairment was. Vegetations can be observed a few days after the onset of symptoms, and often remain after the endocarditis has been cured.

In our study, tricuspid valve fluttering was not always observed in the diagnosis of pulmonary regurgitation (3 of 10 patients), but pulsed Doppler echocardiography was extremely sensitive (all 6 cases).

The clinical course of PV endocarditis depends mainly on which valves are associated. In other reports, the 10 patients with PV endocarditis and left-sided heart involvement[6,8,11,14,15,20,21,27–29] and the 7 patients with PV endocarditis and congenital heart disease[3,4,6,8,11,14] who did not undergo surgery died. However, 7 of 8 patients who received drug treatment for primitive PV endocarditis, whether isolated or associated with tricuspid endocarditis, recovered.[2,16,17,22,23,26]

In PV endocarditis without left-sided cardiac involvement or congenital heart disease, drug treatment usually suffices; surgery is advisable in the case of failure to treat bacterial infection or in right-sided heart failure (usually owing to obstruction of the PV). Pulmonary emboli do not, in our experience, justify surgery in PV endocarditis or in tricuspid endocarditis.[32] Surgery of the PV either involves excision of the vegetations or partial or total excision of the PV if it is destroyed. Residual pulmonary regurgitation is generally well tolerated.[23] Valve replacements are rarely carried out.

Echocardiographic and Doppler Flow Observations in Obstructed and Nonobstructed Hypertrophic Cardiomyopathy

JULIUS M. GARDIN, MD, ALI DABESTANI, MD, GORDON A. GLASGOW, MD, SAMUEL BUTMAN, MD, CORA S. BURN, RN, and WALTER L. HENRY, MD

Some investigators have suggested that left ventricular (LV) ejection is completed much earlier than normal in patients with hypertrophic cardiomyopathy (HC), whether or not a LV outflow gradient is present, and they have therefore concluded that LV ejection is not impeded in HC, but merely ends early because of early completion of LV emptying. This possibility was examined using pulsed Doppler echocardiography to record ascending aortic flow velocity patterns in 20 patients with HC, 12 with evidence of LV outflow gradient at rest (obstructed HC) and 8 without evidence of a significant resting gradient (nonobstructed HC). Peak aortic flow velocity was similar in patients with nonobstructed HC (92 ± 26 cm/s) and those with obstructed HC (94 ± 26 cm/s) and in 20 normal subjects (92 ± 11 cm/s). However, mean ejection time measured from the aortic flow velocity tracing or aortic echogram was longer in those with obstructed HC (345 ± 30 ms) than in those with nonobstructed HC (296 ± 24 ms, $p < 0.02$) and in normal subjects (294 ± 19 ms, $p < 0.01$). Furthermore, a rapid decrease in aortic flow velocity in midsystole was seen in 11 of 12 patients with obstructed HC, but in none of the patients with nonobstructed HC or normal subjects. Doppler left atrial flow velocity recordings, obtained in 11 patients, demonstrated mitral regurgitation in 4 of 5 patients with obstructed HC but in none of 6 patients with nonobstructed HC. The temporal relation between the decrease in Doppler aortic flow velocity, the peaking of Doppler mitral regurgitant flow, and the onset of mitral valve–septal contact in midsystole—as well as observations regarding LV internal dimensional changes—suggest that the early deceleration of aortic blood flow in the patient with obstructed HC is not merely a result of early completion of mechanical systole by a hyperdynamic left ventricle. Rather, midsystolic aortic flow deceleration is at least in part a result of the anterior leaflet of the mitral valve impeding LV outflow and causing ejection of blood by an alternate route into the left atrium. (Am J Cardiol 1985;56:614–621)

Studies of patients with hypertrophic cardiomyopathy (HC) and left ventricular (LV) outflow obstruction have shown that a greater percentage of blood than normal is ejected into the aorta by the left ventricle during the first half of systole.[1–6] One explanation for this finding is that blood is ejected normally in early systole, but by midsystole, subaortic obstruction occurs, which impedes ejection of blood into the aorta. A second explanation is that the left ventricle ejects most, if not all, of its blood volume in early systole, and therefore cannot eject more blood into the aorta in the second half of systole. Arguments for the second explanation are based on studies that suggest that in patients who have HC without LV outflow gradients (nonobstructed), LV ejection is completed early.[2,7]

To further examine the mechanism of LV ejection in patients with obstructed and nonobstructed HC, we used M-mode echocardiography (echo) and combined Doppler/2-dimensional (2-D) echo to evaluate the relation between changes in LV dimension, motion of the aortic and mitral valves, and blood flow velocity patterns in the ascending aorta and left atrium.

Avg Acc = average acceleration; Cath = cardiac catheterization; Dec = deceleration; ET = ejection time; Fam Hx = family history; HC = hypertrophic cardiomyopathy; HR = heart rate; LVFW = left ventricular free wall thickness; LVOT = left ventricular outflow tract gradient at rest; ND = not done; PFV = peak flow velocity; SD = standard deviation; VST = ventricular septal thickness; + = present; − = absent; . . . = not applicable.

43), constitute this group (Table I). All patients had M-mode echocardiograms that showed asymmetric septal hypertrophy; specifically, a ventricular septal thickness of more than 18 mm and a ratio of ventricular septal to LV free wall thickness of more than 1.3 to 1 when thicknesses were measured in diastole below the mitral leaflet tips (Table I). Although some patients had mild systolic anterior motion (SAM) of the mitral valve in systole, in no patient was it severe enough to cause the mitral leaflet to come close to contacting the ventricular septum in systole. The presence of asymmetric septal hypertrophy was confirmed in all patients by 2-D echo. Four of the 8 patients had at least 1 family member with documented HC. Four patients underwent cardiac catheterization which confirmed, in all 4 cases, the absence of a significant (more than 10 mm Hg) LV outflow tract gradient at rest. In addition, all 4 had less than a 30 mm Hg gradient after provocative maneuvers such as isoproterenol, amyl nitrite, the Valsalva maneuver and postpremature ventricular beat. All 4 also underwent LV angiography, which demonstrated a thick-walled left ventricle with near obliteration of the cavity at end-systole. Thus, 7 patients had either a positive family history or catheterization confirmation of the disease. Two patients with nonobstructed HC were taking β-blocking drugs (propranolol), but none was taking calcium-channel blockers.

Obstructed hypertrophic cardiomyopathy: The group of patients with obstructed HC consisted of 5 men and 7 women, aged 16 to 70 years (mean 39). All 12 patients had an M-mode echo demonstrating asymmetric septal hypertrophy and SAM of the mitral valve sufficient to produce prolonged systolic contact between the anterior mitral leaflet and the ventricular septum.[8–10] The echo time period index proposed by Pollick et al[10] was used to estimate the LV outflow tract gradient by the following equation: Pressure gradient (mm Hg) = 25 (index) + 25, where index = duration of SAM–septal contact (ms) divided by the time from onset of SAM to onset of SAM–septal contact (ms) (Table I). The presence of asymmetric septal hypertrophy and septal–mitral contact during systole was confirmed by 2-D echo in all patients.

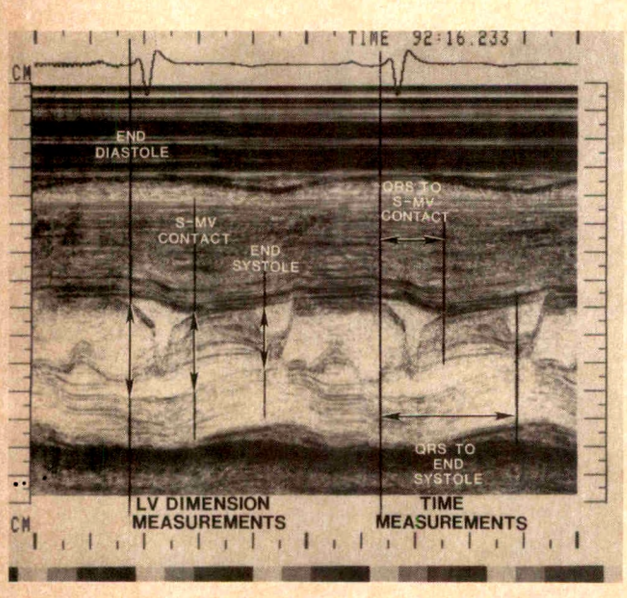

FIGURE 1. M-mode echocardiogram from patient 4, with obstructed hypertrophic cardiomyopathy, labeled to demonstrate left ventricular (LV) dimensional and time measurements. Asymmetric septal hypertrophy and systolic anterior motion of the mitral valve are present. S-MV = ventricular septal–mitral valve.

Eight of the 12 patients had at least 1 family member with documented HC. Four patients in this group had undergone cardiac catheterization and each had an LV outflow gradient at rest of 30 mm Hg or greater (Table I). Eleven patients with obstructed HC were taking β-blocking drugs (propranolol); none was taking calcium-channel blockers.

Normal subjects: Doppler data obtained in the patients with obstructed and nonobstructed HC were compared with data previously obtained in 20 normal subjects. These normal subjects consisted of 12 men and 8 women, ages 21 to 46 years (mean 28).[11]

M-mode echocardiography: M-mode echocardiograms were obtained in the supine or left lateral decubitus positions using a 2.25-MHz, medium-focus transducer with a commercially available echocardiographic module interfaced to a strip-chart recorder (Fig. 1). Ventricular septal and LV free wall thickness and LV internal dimensions were measured in all patients and normal subjects as recommended by the American Society of Echocardiography.[12] In the 12 patients with obstructed HC, 2 additional measurements were made, the time from onset of the QRS complex to initial contact between the mitral valve and the ventricular septum and LV internal dimension at the time of initial contact between the mitral valve and the ventricular septum (Fig. 1).

In 11 of the 12 patients with obstructed HC, adequate M-mode echograms of the aortic valve were obtained. From these echograms, measurements were made from the onset of the QRS complex to the onset of aortic valve opening, maximal midsystolic partial closure of the aortic valve leaflets, and aortic valve closure.

Stop-frame images of the mitral and aortic valve echograms were recorded in the patients with HC at the equivalent of 100 mm/s paper speed.

Doppler echocardiography: All Doppler echo studies were performed with patients at rest using a commercially available ultrasound instrument (Electronics for Medicine/Honeywell Corp.). Using a mapping technique previously described, pulsed Doppler flow velocity recordings were made in the ascending aorta in all 20 patients with HC and 20 normal subjects[11] (Fig. 2). The aortic flow velocity signal used for analysis was that characterized by the greatest maximal flow velocity.

Peak aortic flow velocity, acceleration time, average acceleration, ejection time and a deceleration time index were measured in all patients and normal subjects.[11] Peak flow velocity was determined as the midpoint of the Doppler flow spectrum at the time of maximal flow velocity. Acceleration time was measured from the onset of ejection to the time of peak flow velocity. Average acceleration was calculated by dividing peak flow velocity by acceleration time. Ejection time was measured from the onset to the end of ejection. In 5 patients, 3 with obstructed HC, the end of ejection was difficult to determine from the Doppler aortic flow velocity tracings. In these 5 patients, data for the ejection time were taken from the aortic valve echogram. A Doppler deceleration time index was measured as the time required to decelerate from peak flow velocity to 75% of peak flow velocity. In addition, each aortic flow velocity curve was examined for the presence or absence of a contour characterized by a marked decrease in aortic flow velocity in midsystole with a low flow velocity in mid- to late systole.

In 5 patients with obstructed and in 6 with nonobstructed HC, Doppler flow tracings were recorded behind the mitral valve in the left atrium using an apical 2-chamber or apical 4-chamber 2-D echo image (Fig. 2). Left atrial flow velocity recordings were examined for evidence of mitral regurgitation as indicated by abnormal systolic retrograde flow into the left atrium. In 9 additional patients, left atrial flow velocity could not be measured from the apical approach because the range

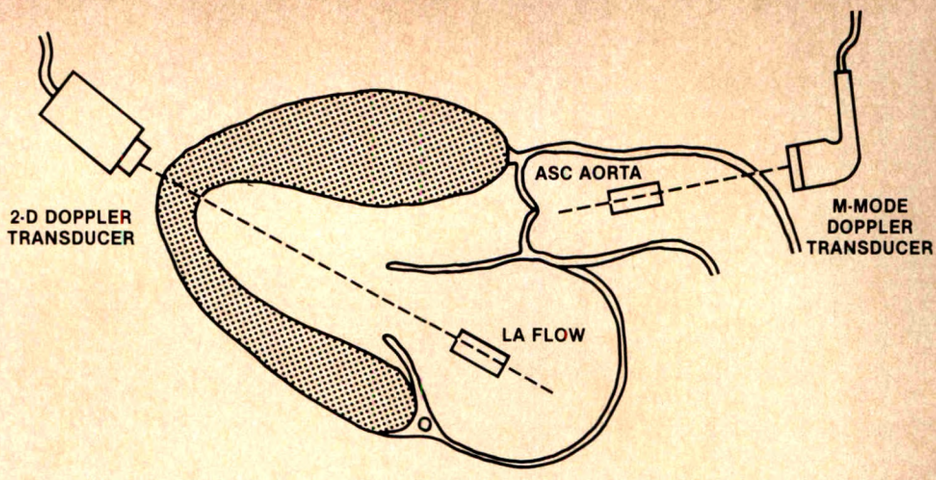

FIGURE 2. Method of recording flow velocity patterns in the ascending (ASC) aorta and left atrium (LA). Two-dimensional (2-D) echo imaging in an apical 2-chamber (or 4-chamber) view is used to position pulsed Doppler sample volumes in the left atrium, whereas a "mapping" technique (without imaging) is used to record ascending aortic flow velocity.

of our pulsed Doppler instrument limited flow recording to a maximal sample depth of 16 cm.

Statistical comparisons: Comparisons of Doppler data among the 3 subgroups (normal subjects, patients with nonobstructed HC and those with obstructed HC) were made using an analysis of variance. A Student t test was used to compare aortic and mitral valve echo timing measurements, or aortic valve echo and Doppler aortic flow timing measurements in the same patient.[13]

Results

Table I is a summary of some of the clinical, M-mode echocardiographic and Doppler data in the patients with obstructed and nonobstructed HC. The septal

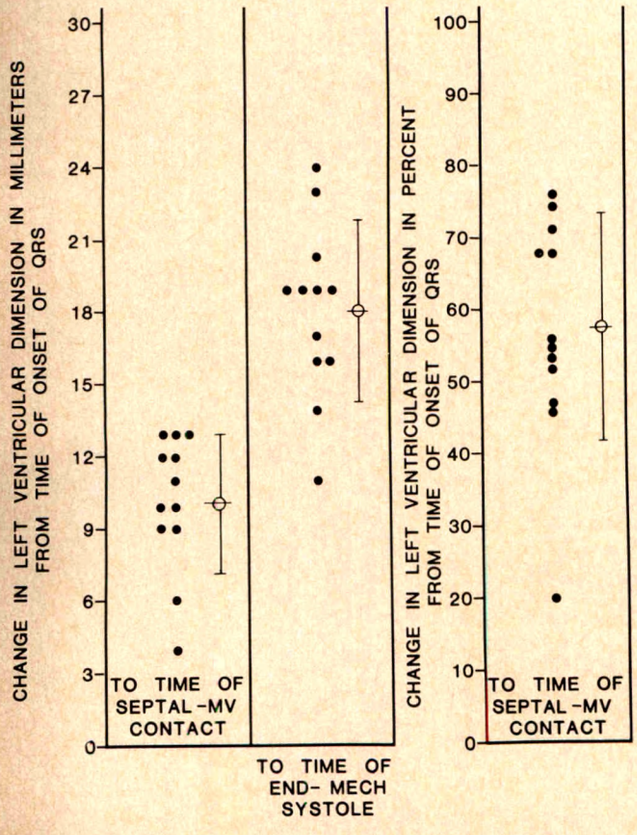

FIGURE 3. Relation between onset of systolic mitral valve (MV)–septal contact and left ventricular (LV) internal dimensional changes in 12 patients with obstructed HC. **Left,** change in LV dimension from time of onset of the QRS complex to time of initial MV–septal contact. **Middle,** change in LV dimension occurring from onset of the QRS to end of mechanical systole. **Right,** change in LV dimension from onset of the QRS to the time of septal–MV contact as a percent of total change in LV internal dimension that occurs from time of onset of QRS to end of mechanical systole. Mean ± SD is shown to the right of each panel.

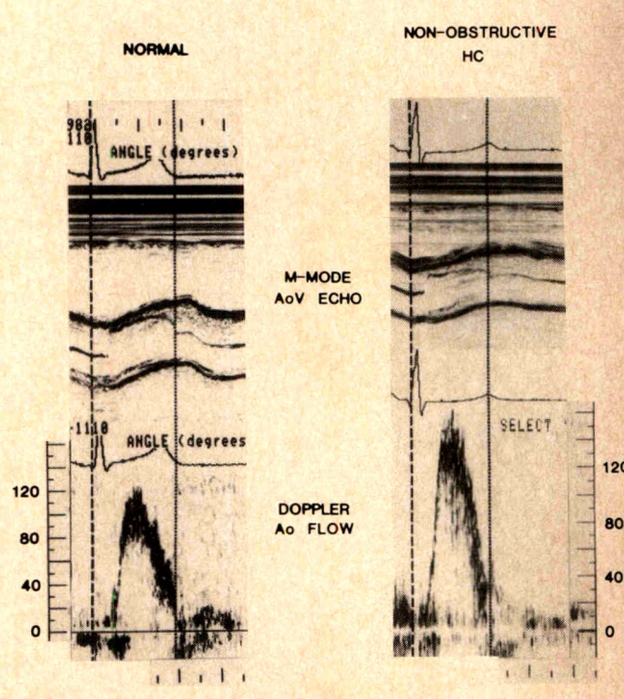

FIGURE 4. Left, aortic valve (AoV) echogram (**top**) and ascending aortic (Ao) flow velocity recording (**bottom**) in a normal subject. Echocardiographic and Doppler flow velocity recordings are matched so that the preceding RR intervals are within 20 ms of each other. **Vertical lines** are drawn at approximately the onset of the QRS complex and at the time of aortic leaflet closure on the aortic valve echogram. Aortic flow begins simultaneous with aortic valve opening, has a smooth limb of acceleration and reaches peak velocity before midsystole. Normal deceleration exhibits a somewhat wider spectrum of flow velocities, but a smooth contour, and ends simultaneous with aortic valve closure. **Right,** aortic valve echogram (**top**) and aortic flow velocity recording (**bottom**) from the same patient as in Figure 2, with nonobstructed hypertrophic cardiomyopathy. Midsystolic partial closure is absent on the aortic valve echogram and there is a normal aortic flow velocity contour.

thickness was at least 19 mm and the septal–free wall ratio was at least 1.7 in each of these patients.

Left ventricular dimensional changes in obstructed hypertrophic cardiomyopathy: Figure 3 shows the relation between SAM of the mitral valve and changes in the LV dimension (minor-axis shortening) in the patients with obstructed HC. The average change in LV dimension at the onset of septal–mitral valve contact as a percent of the total LV dimensional change during electromechanical systole was 58% (range 20 to 76%).

Doppler aortic flow velocity recordings: *Normal subjects and patients with nonobstructed hypertrophic cardiomyopathy:* Figure 4 shows aortic flow velocity tracings and aortic valve echograms from a normal subject and a patient with nonobstructed HC. Aortic flow velocity patterns and aortic valve echograms in both cases have the same contours and temporal relation. Specifically, aortic flow begins at the time of aortic valve opening and shows a smooth acceleration phase to a peak velocity occurring before midsystole. The deceleration phase also exhibits a smooth contour—without a midsystolic rapid deceleration in flow velocity—and ends at the time of aortic valve closure. There is no midsystolic partial closure present on either aortic valve echogram. Aortic peak flow velocity, average acceleration, ejection time and deceleration time index were not significantly different between the normal subjects and the patients with obstructed HC (Table I).

Patients with obstructed hypertrophic cardiomyopathy: In contrast to the normal subjects and patients with nonobstructed HC, a rapid decrease in aortic flow velocity was noted in midsystole in 11 of 12 patients with obstructed HC (Fig. 5 and 6). One patient with

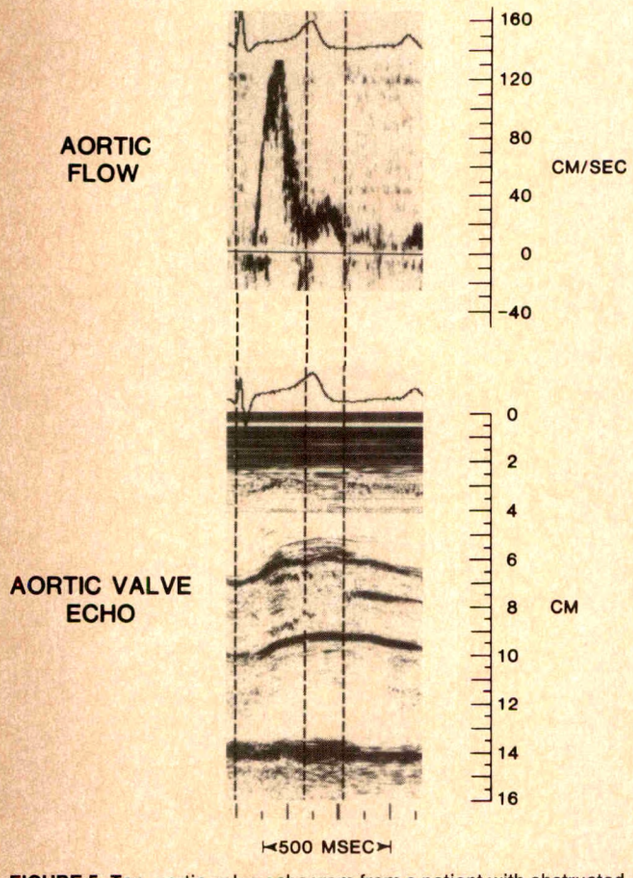

FIGURE 5. Top, aortic valve echogram from a patient with obstructed HC; **bottom,** aortic flow velocity tracing from the same patient. The aortic valve echogram and flow velocity recording are matched so that the preceding RR intervals are within 20 ms of each other. Characteristic partial midsystolic closure is seen on the aortic valve echogram. **Vertical lines** are drawn at the time of onset of QRS complex, Doppler aortic midsystolic flow velocity nadir, and end of ejection on the Doppler flow velocity tracing. The nadir in midsystolic aortic flow velocity occurs at about the time of maximal midsystolic partial closure of the posterior aortic leaflet (noncoronary cusp), but well before aortic valve closure. The end of ejection on the Doppler tracing occurs nearly simultaneous with aortic valve closure.

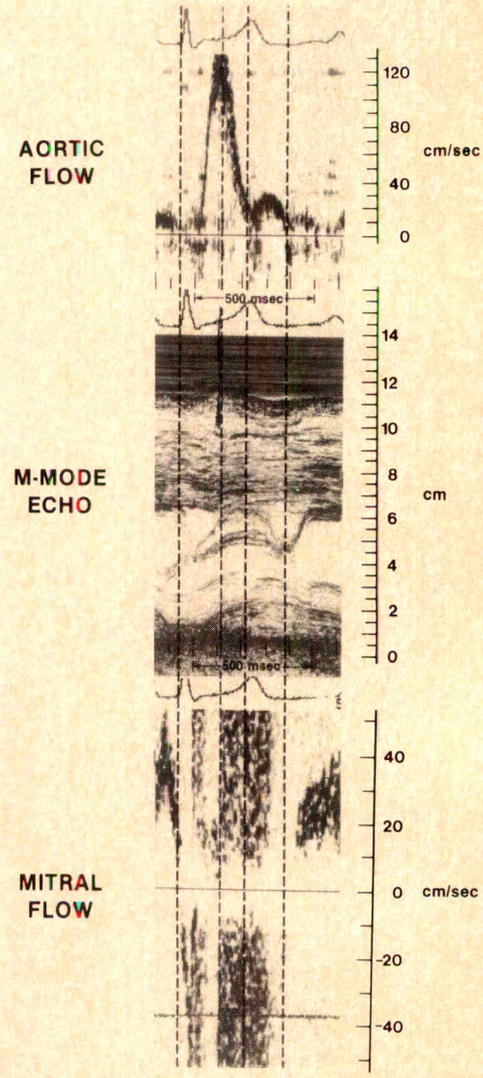

FIGURE 6. Temporal sequence of systolic events in obstructed hypertrophic cardiomyopathy. **Dashed vertical lines** are drawn at the onset of QRS, onset of systolic anterior motion–septal contact, midsystolic aortic flow velocity nadir, and end of ejection on the aortic flow velocity recording. Flow velocity recorded in the left atrium near the level of the mitral valve shows turbulent systolic flow consistent with mitral regurgitation (**bottom**). M-mode echocardiogram at the level of the mitral valve shows septal–mitral valve contact (**middle**). Ascending aortic flow velocity recording shows a rapid midsystolic flow velocity deceleration (**top**). These 3 records, from patient 12, were matched such that the preceding RR intervals were within 20 ms of each other.

obstructed HC had a normal-appearing aortic flow velocity contour without a rapid decrease in flow velocity in midsystole.

Mean heart rate, peak aortic flow velocity and average acceleration were not statistically different in the 3 groups (Table I). However, mean ejection time was greater in patients with obstructed HC (mean 345 ± 30 ms) than in those with nonobstructed HC (296 ± 24 seconds, $p < 0.02$) and the normal subjects (294 ± 19 ms, $p < 0.01$) (Fig. 7). There was no significant difference in ejection time between the patients with nonobstructed HC and normal subjects, even after ejection time was corrected for heart rate using a formula described by Weissler et al[14] for external carotid pulse tracings.

We also measured ejection time from the aortic valve echogram in the same patients (Fig. 4 and 5). Paired measurements of ejection time calculated from Doppler aortic flow tracings and from aortic valve echograms were not significantly different. In 13 of the 14 patients, ejection time measured by the 2 methods did not differ by more than 20 ms.

Data for the deceleration time index, summarized in Table I, reflect a significantly shorter index in patients with obstructed HC (64 ± 22 ms) than in those with nonobstructed HC (96 ± 19 ms) or normal subjects (94 ± 12 ms) ($p < 0.001$). This difference reflects the more rapid early deceleration of aortic flow velocity in patients with obstructed HC.

M-mode echo/Doppler aortic flow relationships in obstructed hypertrophic cardiomyopathy: Figure 8 is a summary of the temporal relations between the onset of mitral valve–septal contact, aortic valve midsystolic partial closure, the initial nadir in Doppler flow velocity and total electromechanical systole as measured from the onset of QRS to end of ejection. In the 11 patients with obstructed HC and rapid midsystolic decrease in aortic flow velocity, the time from onset of QRS to initial systolic contact of mitral valve and septum averaged 218 ms (range 135 to 300), while the time from onset of QRS to maximal midsystolic partial closure of aortic valve leaflets averaged 244 ms (range 155 to 350). These 2 measurements were statistically similar and suggest that the onset of septal–mitral valve contact and midsystolic partial closure on the aortic valve

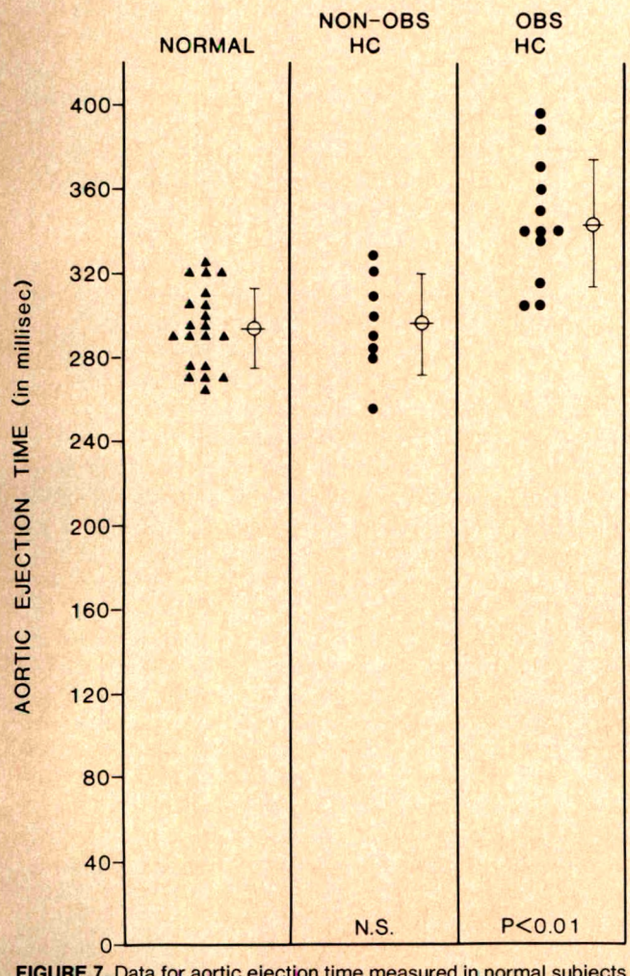

FIGURE 7. Data for aortic ejection time measured in normal subjects and patients with nonobstructed (NON-OBS) and obstructed (OBS) hypertrophic cardiomyopathy (HC). In the patients with obstructed HC, ejection time measurements were plotted from the Doppler aortic flow tracings in 9 patients and from the aortic valve echogram in 3.

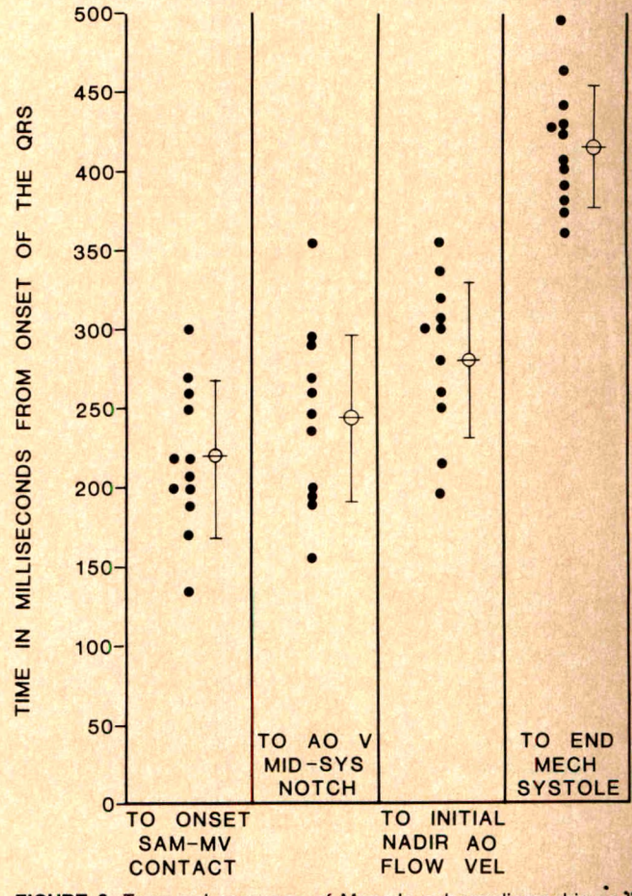

FIGURE 8. Temporal sequence of M-mode echocardiographic and Doppler aortic flow velocity events in patients with obstructive hypertrophic cardiomyopathy. The 4 panels show data for the time from onset of QRS complex to the onset of mitral valve-septal contact (SAM–MV), aortic valve partial midsystolic closure (maximal) (AO V MID-SYS NOTCH), midsystolic nadir on the Doppler aortic flow velocity (AO FLOW VEL curve), and end of ejection (END MECH SYSTOLE). Data in the middle 2 panels is plotted for only the 11 patients who had partial midsystolic closure on the aortic valve echogram and a midsystolic rapid deceleration in the aortic flow velocity.

echogram are nearly simultaneous events. The time from onset of QRS to the midsystolic nadir on the Doppler aortic flow velocity curve averaged 284 ms (range 195 to 355) which was an average of 40 ms after midsystolic partial closure on the aortic valve echogram and 66 ms after the onset of mitral valve–septal contact. The time from onset of QRS to end of ejection averaged 417 ms (range 360 to 495). Thus, the time from onset of QRS to onset of mitral valve–septal contact, aortic valve midsystolic partial closure, and midsystolic flow velocity nadir all averaged between one-half and two-thirds of the time of total electromechanical systole.

Left atrial flow velocity recording: Doppler flow velocity tracings were recorded in the left atrium in 5 patients with obstructed and 6 patients with nonobstructed HC. Four of 5 patients with obstructed HC, but none of 6 patients with nonobstructed HC, had mitral regurgitation. Figure 6 (bottom) is a left atrial flow velocity recording from patient 12, who had obstructed HC. Diastolic flow above the 0 line represents blood flow in the normal direction from left atrium to left ventricle; turbulent systolic flow above and below this line represents regurgitant flow into the left atrium. Mitral regurgitation (intensity of turbulence) is most prominent after the time of septal–mitral valve contact.

Summary of temporal sequence in obstructed hypertrophic cardiomyopathy: Figure 6 shows the sequence of events in a patient with obstructed HC. All 3 records, from the same patient, were matched such that the preceding RR intervals for each beat were within 20 ms of each other. The onset of LV posterior wall motion and the onset of aortic ejection were initial and near-simultaneous events. The next event was the attainment of peak aortic flow velocity, followed by the onset of mitral valve–septal contact and turbulent flow in the left atrium, and the rapid deceleration of aortic blood flow velocity in midsystole. Mitral regurgitation is recorded until just before the end of mitral valve–septal contact.

Discussion

Our echo Doppler studies demonstrate several differences between patients with obstructed HC and those with nonobstructed HC. First, although Doppler ascending aortic flow velocity patterns in patients with nonobstructed HC and normal subjects were similar, patterns in patients with obstructed HC differed from those in normal subjects and patients with nonobstructed HC. Specifically, the abnormal flow pattern, seen in 11 of 12 patients with obstructed HC, consisted of a rapid decrease in aortic flow velocity in midsystole, and was not seen in any of the patients with nonobstructed HC or normal subjects. Quantitatively, the patients with obstructed HC had a higher mean ejection time (345 ms) than those with nonobstructed HC (296 ms, $p < 0.02$) or normal subjects (294 ms, $p < 0.01$). Furthermore, the deceleration time index (i.e., the time from peak to 75% of peak flow velocity) was significantly shorter in patients with obstructed HC than in those with nonobstructed HC or normal subjects ($p < 0.001$).

The abnormal pattern of aortic blood flow velocity in patients with obstructed HC was first described by Hernandez et al,[3] who used intraaortic pressure gradient recordings. They noted that peak velocity occurred in early systole and was followed by an abrupt decrease in flow velocity at midsystole, with a diminished late systolic velocity. Other investigators, using electromagnetic flowmeters in patients with obstructed HC, have reported similar findings in the aorta[5] and brachial artery.[6]

Joyner et al[15] used continuous-wave Doppler to record phasic carotid artery flow transcutaneously in 12 patients with obstructed HC. All of their patients showed a rapid rise to a peak in early systole, an abrupt decrease in carotid flow velocity in midsystole and a slow late systolic flow wave. Boughner et al[16] used a continuous-wave Doppler transducer in the suprasternal notch to record flow velocity in the aortic arch in 3 patients with HC.[16] In 1 patient with a LV outflow gradient at rest, the aortic flow velocity pattern was characterized by a sharp early peak followed by a rapid decrease in velocity in midsystole, and a second lower peak in late systole. In 2 patients with HC without an LV outflow gradient, a normal aortic flow velocity tracing was noted.

As in these studies, we also found, in the patients with obstructed HC, an initial peak in flow velocity followed by a fall in midsystole to a lower velocity in late systole and in our patients with nonobstructed HC, a normal flow velocity pattern. The early reduction of ascending aortic blood flow velocity in the patients with obstructed HC does not appear to be merely a result of early completion of mechanical systole by a hyperdynamic left ventricle. This conclusion is supported by several observations. First, ejection time as measured by 2 independent methods (Doppler aortic flow velocity curves and aortic valve echograms) was longer in patients with obstructed HC than in those with nonobstructed HC or normal subjects. Second, LV minor-axis shortening on M-mode echo continued after both the initial mitral valve–septal contact and the midsystolic nadir of aortic blood flow velocity. Third, analysis of left atrial flow velocity recordings indicated that early deceleration of aortic blood flow velocity in midsystole appears to be a result of SAM of the mitral valve, which also results in mitral regurgitation.[17,18] Wigle et al[17] found that all 33 of their patients with HC and LV outflow gradients had evidence of mitral regurgitation by indicator-dilution techniques.[17]

Our findings differ from those recently reported by Murgo et al.[2] They studied 30 patients with HC and 29 patients with no evidence of cardiovascular disease. LV angiograms were recorded in all patients. A multisensor catheter was used to determine ascending aortic flow velocity electromagnetically as well as high-fidelity LV and aortic pressures. The 30 patients with HC included 9 with intraventricular pressure gradients at rest, 12 with pressure gradients only with provocation, and 9 with no pressure gradients despite provocation. These investigators found no significant differences between any of the 3 HC subgroups in either aortic ejection time or the time during which forward aortic flow occurred as a percentage of total systolic ejection period. They concluded that outflow obstruction, as traditionally defined by the presence of an abnormal intraventricular

pressure gradient and systolic anterior motion of the mitral valve, does not impede LV outflow in HC.

Although Murgo et al concluded that LV ejection times were not different in patients with obstructed HC, those with nonobstructed HC and normal subjects, their actual mean values for ejection times were similar to our measurements. In their study, systolic ejection times, measured from electromagnetic flow analysis, averaged 322 ± 32 ms in the group with LV gradients, 292 ± 28 ms in the group without gradients, and 286 ± 32 ms in normal subjects. Ejection times in our study averaged 345 ± 30 ms in the group with obstructed HC, 296 ± 24 ms in the group with nonobstructed HC and 294 ± 19 ms in normal subjects. When Murgo et al measured ejection times using frame-by-frame analysis of LV angiograms, they found a highly significant difference ($p < 0.001$) between values in HC patients with gradients (356 ± 53 ms), and both HC patients without gradients (303 ± 13 ms) and normal subjects (278 ± 36 ms). Two other studies have found ejection time to be significantly greater than normal in patients with HC and LV outflow gradients.[4,19]

There are several possible explanations for the different conclusions reached by us and Murgo et al. First, not all patients with HC in our study underwent cardiac catheterization. However, all had asymmetric septal hypertrophy (septal–free wall ratio of 1.7 or greater and an absolute septal thickness of at least 19 mm), as well as echo evidence suggesting an LV outflow tract pressure gradient of 45 mm Hg or greater (using the obstruction index of Pollick et al[10]). In view of the published experience showing a good correlation between echo and angiographic observations in HC, the lack of catheterization data in every patient in the present study probably does not account for the differences between the 2 studies. Moreover, 7 of the 8 patients with nonobstructed HC in the current study had either a positive family history or catheterization confirmation of the disease. A second difference between the 2 studies is that Murgo et al used angiographic and electromagnetic flow measurements to estimate ejection time, whereas we used measurements from the Doppler flow tracings and aortic valve echograms. Also, conclusions about LV shortening were made from angiographic measurements in their study, whereas our conclusions are based on dimensional changes measured from echocardiograms.

It is important to consider 2 factors that theoretically may have played a role in the longer mean ejection time in the patients with obstructed HC compared with values in patients with nonobstructed HC and normal subjects. First, both the patients with obstructed and nonobstructed HC were older (mean 39 to 43 years, respectively) than the 20 normal subjects (mean age 28 years). However, in a recent preliminary report, age had no effect on the aortic ejection time measured from Doppler aortic flow velocity tracings in 95 subjects without evidence of cardiovascular disease.[20] Second, the fact that 11 of the 12 patients with obstructed HC were taking propranolol, whereas only 2 of the 8 patients with nonobstructed HC were taking this drug, may have resulted in the longer mean ejection time in the patients with obstructed HC. However, heart rates were not significantly different between patients with obstructed HC (mean 64 ± 10 beats/min) and those with nonobstructed HC (58 ± 9 beats/min). Furthermore, no patient taking propranolol had evidence of a subnormal LV ejection fraction by echo or LV angiography. Consequently, although propranolol treatment may have had some effect, it is unlikely that it was responsible for the significant differences in ejection time between our patients with obstructed HC and those with and nonobstructed HC.

Instructions to Authors

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY, that upon submission, they become the property of the Publisher, that the work has not been previously published, and that the data in the manuscript have been reviewed by all authors, who agree with the analysis of the data and the conclusions reached in the manuscript. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced without the written permission of the Publisher. Statements in articles are the responsibility of the authors.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 7960 Old Georgetown Road, Suite 2C, Bethesda, Maryland 20814. The covering letter should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make (for example, the elimination of 1 or more figures or tables or a portion of the text) to increase the likelihood of publication of their work in the *Journal.* Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The names of investigators considered unlikely by the authors to give nonbiased reviews of their work may also be submitted.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript, including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page, which should include the title, the full names and academic degrees of the authors, and the institution and city and state or city and country from which the work originated; (2) second title page, with only the title of the article; (3) miniabstract for Table of Contents that includes the full title and names of all authors; (4) abstract; (5) text; (6) references; (7) acknowledgment; (8) figure legends; and (9) tables. Number all pages in the above sequence, beginning with the title page as 1, the abstract as 2, and so on. (Leave the second title page and the miniabstract unnumbered.) Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references), with at least 25-mm (1-inch) margins.

The second title page, on which the names and institution of the authors are omitted, gives the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be solicited. The authors should state which type of review they wish in the covering letter; this request is always honored.

TITLE PAGE, TABLE OF CONTENTS ABSTRACT AND MINIABSTRACT: For the **complete title page,** include the full first or middle and last names of all authors. Provide a short running title of 3 to 6 words. List the institution and address from which the work originated, and provide information about grant support if necessary. Add at the bottom the phrase, "Address for reprints:" followed by full name and address with zip code.

Limit the **abstract** to 250 words and the Table of Contents **miniabstract** to 150 words. List 2 to 6 **key words** for subject indexing at the end of the abstract.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as the Methods, Results and Discussion. **Abbreviations** are permitted, but no more than 4 per manuscript, and then they must be used on every page of the manuscript after they are initially spelled out (followed by the abbreviation) in both abstract and introduction. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence, but try not to begin sentences with numbers. Use symbols for less than (<), greater than (>) and percent (%). Indent for paragraphs except the first one in both abstract and introduction. Consult the Uniform Requirements for Manuscripts Submitted to Biomedical journals, published in *The Annals of Internal Medicine* June 1982;96:766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage.

REFERENCES: List all authors, year, volume and inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts, but if they are used, indicate them as such by the abbreviation (abstr) after the title. Do not use periods after authors' initials or after abbreviations for titles of journals. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications, unpublished observations, and manuscripts submitted but not yet accepted for publication do not constitute references.

Journal: Harvey W, Heberden W, Withering W, Stokes W, Murrell W, Einthoven W, Osler W. Anomalies and curiosities of cardiology and of cardiologists. Reflections of famous medical Williams. Am J Cardiol 1984;53:900–915.

Chapter in Book: Cabot RC, White PD, Taussig HB, Levine SA, Wood P, Friedberg CK, Nadas AS, Hurst JW, Braunwald E. How to write cardiologic textbooks. In: Hope JA, ed. A Treatise on Disease of the Heart and Great Vessels. London: Yorke Medical Books, 1984;175–200.

Book: Carrel A, Cutler EC, Gross RE, Blalock A, Craffoord C, Brock RC, Bailey CP, DeBakey ME. The Closing of Holes, Replacing of Valves and Inserting of Pipes, or How Cardiovascular Surgeons Deal with Knives, Knaves and Knots. New York: Yorke University Press, 1984:903.

FIGURES: Submit 3 glossy, unmounted prints of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all charts (line drawings). Make decimals, broken lines, and so on, clear enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by title of the article; omit the authors' names so that blinded reviews can be obtained. Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce previously published figures. Limit figures to the number necessary to present the message clearly. Type **figure legends** on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author.

TABLES: Place each table on a separate page, typed double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating numbers of patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate "positive" or "present," a zero (0) for "negative" or "absent," and dash (—) for "no information available" or "not done." Do not use "yes" or "no."

BRIEF REPORTS: Brief Reports must be limited to no more than 3 text pages and 6 references. Longer ones usually will be returned without review. Neither an abstract nor a Table of Contents miniabstract is required for a Brief Report. Subheadings are not used in the body of the Brief Report.

LETTERS (For Publication): The author who submits a letter for consideration for publication should provide a covering letter on his/her own stationery to the Editor-in-Chief stating why the letter should be published. The letter for consideration for publication should be typed, double-spaced, on a separate sheet of plain white paper and limited, with few exceptions, to 2 pages. The original and 2 xerographic copies should be submitted. A title for the letter should be provided at the top of the page. At the end of the letter, the writer's full name and city and state (or country if outside the United States) should be provided. The author's title and institution should not be included. The word "References" does not appear above the list of references in published letters. References should be double-spaced. A letter concerning a particular article in the *Journal* must be received (from authors within the United States) within 2 months of the article's publication.

REPRINTS: Price schedules and order cards for reprints are mailed to the author upon publication of the article. Individual reprints must be obtained through the author.

For successful monotherapy in angina

Recent evidence[1] has shown that optimal results with ISORDIL (isosorbide dinitrate) are achieved when the entire dosage range is utilized: **Start with 10 or 20 mg q.i.d. before meals and at bedtime and increase to 30 mg q.i.d. or until an optimal result is obtained.** ***Isordil® Titradose® has been approved for use at 40 mg q.i.d.***

ISORDIL® TITRADOSE®

Ives®

In angina pectoris...

Give enough to do the job

ISORDIL®
(ISOSORBIDE DINITRATE)

Contraindications: Hypersensitivity or idiosyncrasy to this drug or other nitrates or nitrites.
Warnings: Benefits of use during the early days of an acute myocardial infarction have not been established; if used in early infarction, hemodynamic monitoring and frequent clinical assessment should be made because of the potential deleterious effects of hypotension.
Precautions: *General.* Severe hypotensive response, particularly with upright posture, may occur even with small doses; therefore use caution in subjects with blood volume depletion from diuretic therapy or with low systolic blood pressure (eg, below 90 mm Hg). Paradoxical bradycardia and increased angina pectoris may accompany nitrate-induced hypotension. Nitrates may aggravate angina caused by hypertrophic cardiomyopathy. Tolerance to this drug and cross-tolerance to other nitrates and nitrites may occur. Marked symptomatic, orthostatic hypotension has been reported when calcium channel blockers and organic nitrates were used in combination; dose adjustment of either class of agents may be necessary. There are reports of anginal attacks being more easily provoked and of rebound in hemodynamic effects soon after nitrate withdrawal; when therapy is being terminated, withdraw the drug gradually rather than stopping it abruptly.
Information for Patients. Headache may occur during initial therapy; it is usually relieved by standard headache remedies, or by lowering the dose, and tends to disappear after the first week or two of use.
Drug Interactions. Alcohol may enhance any marked sensitivity to the hypotensive effect of nitrates. Isosorbide dinitrate acts directly on vascular smooth muscle; therefore, any other agent that depends on vascular smooth muscle as the final common path can be expected to have decreased or increased effect, depending on the agent.
Carcinogenesis, Mutagenesis, Impairment of Fertility. No long-term studies in animals have been performed.
Pregnancy Category C. Use during pregnancy only if the potential benefit justifies the potential risk to the fetus.
Nursing Mothers. It is not known whether this drug is excreted in human milk; because many drugs are excreted in human milk, caution should be exercised in nursing women.
Pediatric Use. Safety and effectiveness in children have not been established.
Adverse Reactions: Adverse reactions, particularly headache and hypotension, are dose related. At various doses, the following have been observed:
Headache is the most common (average occurrence about 25%) and may be severe and persistent. Cutaneous vasodilation with flushing may occur. Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension, may occasionally develop (the incidence of reported symptomatic hypotension ranges from 2% to 36%). An occasional individual will exhibit marked sensitivity to the hypotensive effects of nitrates, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration, and collapse) may occur even with the usual therapeutic dose. Drug rash and/or exfoliative dermatitis may occasionally occur. Nausea and vomiting appear to be uncommon.
Overdosage: *Treatment.* Prompt removal of the ingested material by gastric lavage is reasonable but not documented to be useful. Keep the patient recumbent in a shock position and comfortably warm. Passive movements of the extremities may aid venous return. Administer oxygen and artificial respiration if necessary. If methemoglobinemia is present, administer methylene blue (1% solution), 1 to 2 mg/kg intravenously. *WARNING:* Epinephrine is ineffective in reversing the severe hypotensive events associated with overdose. It and related compounds are contraindicated in this situation.
Consult direction circular before prescribing.

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC
Henry N. Neufeld, MD, FACC
1978, 288 PAGES, 110 ILLUS., 1,000 REF.

Every Cardiologist, Internist, Pediatrician, Surgeon — Indeed, *Every Physician* — Should Have a Good Basic Knowledge of The Pre-excitation Syndrome. Here Are Just a Few Reasons Why This is so Essential:

- ⅓ of all pre-excitation cases are misdiagnosed.
- 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies on patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals

The 13 Chapters Are a Comprehensive Summary

1. General Considerations
2. The Electrocardiogram in the Pre-excitation Syndrome: Complexes and Configurations
3. The Electrocardiogram in the Pre-excitation Syndrome: Disturbances of Rate and Rhythm
4. Pathology
5. Noninvasive Methods of Investigation
6. Invasive Methods of Investigation
7. Prognosis
8. Treatment
9. Problems of Diagnosis — Some Illustrative Cases
10. Summary of Findings and Theories of Pre-excitation Syndrome
11. Concept of Interacting Structural and Functional Factors
12. Explanation of Some Phenomena of the Pre-excitation Syndrome by the Proposed Concept
13. Various QRS Patterns in the Different Forms of Pre-excitation

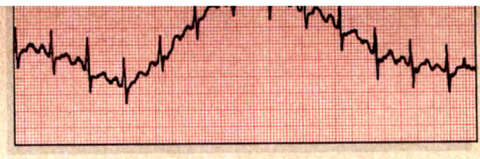
preparation system Quik-Prep™ because it makes prepping the patient faster. But one look at the traces on the right will tell you we could have named it Stable Baseline Prep. Both traces were from the same patient, the same day, with the same equipment.

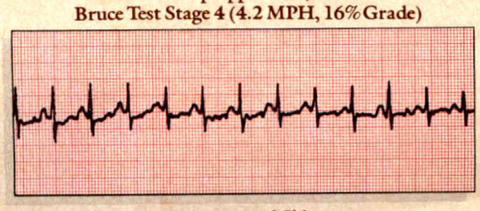
Consistently better ECG traces.

Proper skin preparation is the key to stable baselines. And Quik-Prep is the key to proper skin preparation.

Quik-Prep's patented applicator rotates the center of a special pre-gelled silver-silver chloride electrode. By measuring the electrical impedance of the skin electrode combination, it literally senses when the skin is properly prepared so you get stable ECG baselines, test after test.



Unprepped skin,
Bruce Test Stage 4 (4.2 MPH, 16% Grade)



Quik-Prepped Skin,
Bruce Test Stage 4 (4.2 MPH, 16% Grade)

What's more, Quik-Prep won't overabrade the skin, so your patients will have less pain, less anxiety, less trauma.

Like the name says, Quik-Prep's fast. In most cases, ten electrodes can be prepped in less than three minutes.

You save expensive technician time every test. And you won't waste either time or supplies repeating tests because the skin wasn't properly prepped. That gives Quik-Prep a lower cost-in-use than most standard electrodes.

We'd like to show you how Quik-Prep's skin preparation system can give you better ECG traces, more efficiently. For a free demonstration, call Quinton at 1-800-431-1114 or write us at 2121 Terry Ave., Seattle, WA 98121 • Telex 3794094.

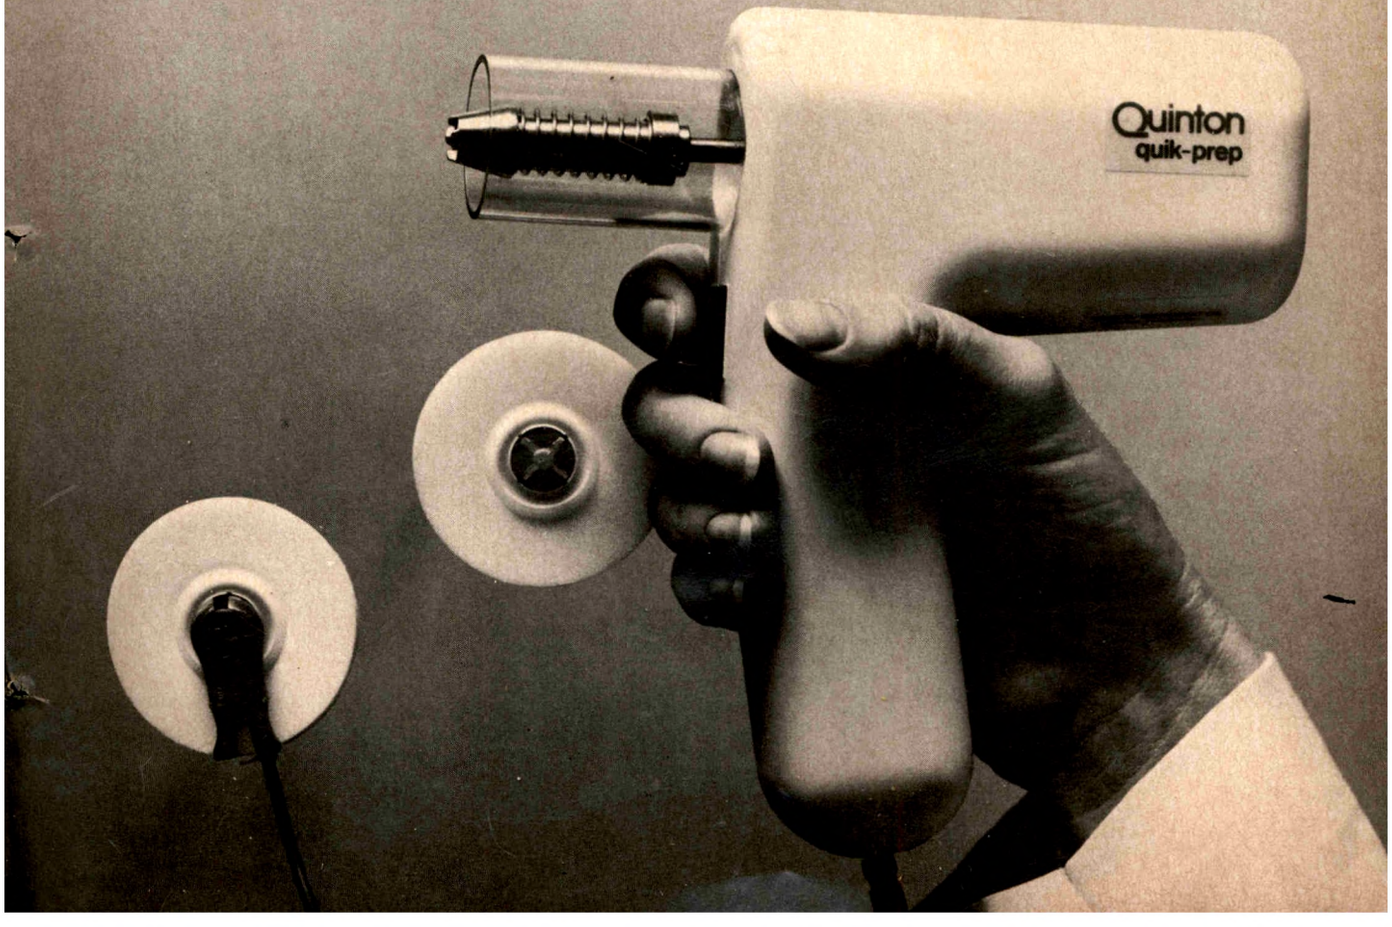
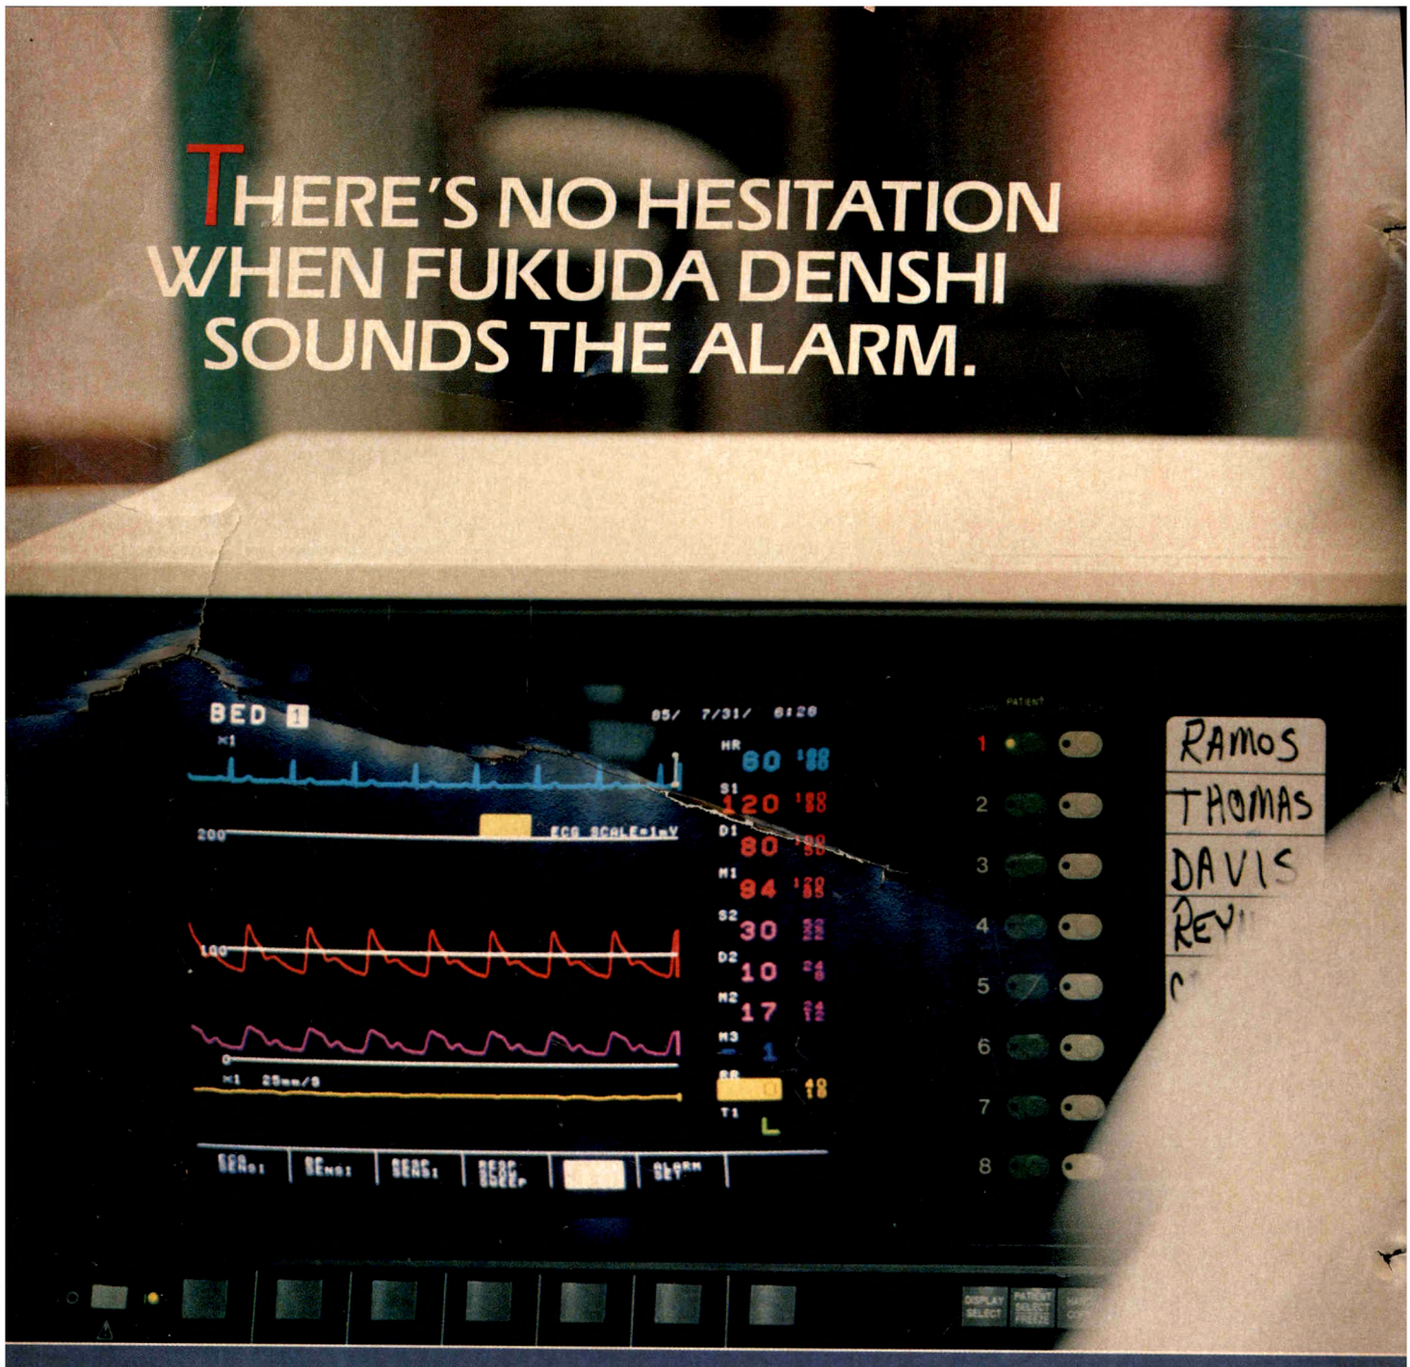
WE COULD HAVE CALLED IT "STABLE BASELINE PREP."



THERE'S NO HESITATION WHEN FUKUDA DENSHI SOUNDS THE ALARM.



It's imperative to have full confidence in your patient monitors to make accurate, split second decisions.

If your present system is prone to false alarms, everything else that equipment displays falls under a cloud of suspicion.

We don't think it's asking too much to have patient monitors that function as promised. That's why we're dedicated to performance that deserves your complete trust.

From the comprehensive range of Fukuda Denshi instruments, you can choose the optimum combination of parameters at the right price.

For a fast and accurate grasp of a patient's condition, every monitor displays a precise picture of vital signs on an ultra-high resolution screen. At the central station, each parameter is color coded for positive identification. And numerical data are shown bold and large to be instantly recognized.

Simple, straightforward operation of our monitors is assured by careful human engineering. So you can easily utilize all the advanced features of a Fukuda system without delay or confusion.

...and protecting healing hearts in the months ahead

The combination of early intravenous administration of Lopressor followed by long-term oral therapy resulted in a 36% reduction of three-month mortality in patients with definite or suspected acute MI in the Göteborg Trial.[1]

Alternatively, oral treatment can begin within 3 to 10 days of the acute event.

Treatment should be continued for 1-3 years.

Lopressor is contraindicated in patients with a heart rate <45 beats/min; significant heart block greater than first degree (P-R interval ≥0.24 sec); systolic blood pressure <100 mmHg; or moderate-to-severe cardiac failure. Please see last page for Brief Summary of Prescribing Information.

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE
Myocardial Infarction
Lopressor ampuls, prefilled syringes and tablets are indicated in the treatment of hemodynamically stable patients with definite or suspected acute myocardial infarction to reduce cardiovascular mortality. Treatment with intravenous Lopressor can be initiated as soon as the patient's clinical condition allows (see **DOSAGE AND ADMINISTRATION, CONTRAINDICATIONS,** and **WARNINGS**). Alternatively, treatment can begin within 3 to 10 days of the acute event (see **DOSAGE AND ADMINISTRATION**).

CONTRAINDICATIONS
Myocardial Infarction
Lopressor is contraindicated in patients with a heart rate < 45 beats/min; significant heart block greater than first degree (P-R interval ≥ 0.24 sec); systolic blood pressure < 100 mmHg; or moderate-to-severe cardiac failure (see **WARNINGS**).

WARNINGS

Myocardial Infarction
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function, and beta blockade carries the potential hazard of depressing myocardial contractility and precipitating or exacerbating minimal cardiac failure.

During treatment with Lopressor, the hemodynamic status of the patient should be carefully monitored. If heart failure occurs or persists despite appropriate treatment, Lopressor should be discontinued.

Bradycardia: Lopressor produces a decrease in sinus heart rate in most patients; this decrease is greatest among patients with high initial heart rates and least among patients with low initial heart rates. Acute myocardial infarction (particularly inferior infarction) may in itself produce significant lowering of the sinus rate. If the sinus rate decreases to < 40 beats/min, particularly if associated with evidence of lowered cardiac output, atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, Lopressor should be discontinued, and cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

AV Block: Lopressor slows AV conduction and may produce significant first- (P-R interval ≥0.26 sec), second-, or third-degree heart block. Acute myocardial infarction also produces heart block.

If heart block occurs, Lopressor should be discontinued and atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

Hypotension: If hypotension (systolic blood pressure ≤ 90 mmHg) occurs, Lopressor should be discontinued, and the hemodynamic status of the patient and the extent of myocardial damage carefully assessed. Invasive monitoring of central venous, pulmonary capillary wedge, and arterial pressures may be required. Appropriate therapy with fluids, positive inotropic agents, balloon counterpulsation, or other treatment modalities should be instituted. If hypotension is associated with sinus bradycardia or AV block, treatment should be directed at reversing these (see above).

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative $beta_1$ selectivity, Lopressor may be used with extreme caution in patients with bronchospastic disease. Because it is unknown to what extent $beta_2$-stimulating agents may exacerbate myocardial ischemia and the extent of infarction, these agents should *not* be used prophylactically. If bronchospasm not related to congestive heart failure occurs, Lopressor should be discontinued. A theophylline derivative or a $beta_2$ agonist may be administered cautiously, depending on the clinical condition of the patient. Both theophylline derivatives and $beta_2$ agonists may produce serious cardiac arrhythmias.**

PRECAUTIONS
General
Lopressor should be used with caution in patients with impaired hepatic function.

Information for Patients
Patients should be advised to take Lopressor regularly and continuously, as directed, with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Lopressor without consulting the physician.

Patients should know how they react to this medicine before they operate automobiles and machinery or engage in other tasks requiring alertness. Patients should contact the physician if any difficulty in breathing occurs, and before surgery of any type, the patient should inform the physician or dentist that he or she is taking Lopressor.

Laboratory Tests
Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.

Drug Interactions
Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a 1-year study in dogs, there was no evidence of drug-induced toxicity at or below oral dosages of 105 mg/kg per day. In 2-year studies in rats at three oral dosage levels of up to 800 mg/kg per day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dosage levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.

Pregnancy Category B
Reproduction studies have been performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg and have revealed no evidence of impaired fertility or teratogenicity due to Lopressor. Increased postimplantation loss and decreased neonatal survival did occur in the rats (threshold between 50 and 500 mg/kg), and distribution studies in mice confirm exposure of the fetus when Lopressor is administered to the pregnant animal. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers
Lopressor is excreted in breast milk in very small quantity. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Lopressor is administered to a nursing woman.

Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Myocardial Infarction
Central Nervous System: Tiredness has been reported in about 1 of 100 patients. Vertigo, sleep disturbances, hallucinations, headache, dizziness, visual disturbances, confusion, and reduced libido have also been reported, but a drug relationship is not clear.

Cardiovascular: In the randomized comparison of Lopressor and placebo described in the **CLINICAL PHARMACOLOGY** section, the following adverse reactions were reported:

	Lopressor	*Placebo*
Hypotension (systolic BP < 90 mmHg)	27.4%	23.2%
Bradycardia (heart rate < 40 beats/min)	15.9%	6.7%
Second- or third-degree heart block	4.7%	4.7%
First-degree heart block (P-R ≥ 0.26 sec)	5.3%	1.9%
Heart failure	27.5%	29.6%

Respiratory: Dyspnea of pulmonary origin has been reported in fewer than 1 of 100 patients.

Gastrointestinal: Nausea and abdominal pain have been reported in fewer than 1 of 100 patients.

Dermatologic: Rash and worsened psoriasis have been reported, but a drug relationship is not clear.

Miscellaneous: Unstable diabetes and claudication have been reported, but a drug relationship is not clear.

Potential Adverse Reactions
A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Lopressor.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

Primary Acute Pericardial Disease: A Prospective Series of 231 Consecutive Patients

G. PERMANYER-MIRALDA, MD, J. SAGRISTÁ-SAULEDA, MD, and J. SOLER-SOLER, MD

A series of 231 patients with "primary" acute pericardial disease (acute pericarditis or tamponade presenting without an apparent cause) were studied according to the following protocol: general clinical and laboratory studies (stage I), pericardiocentesis (stage II), pericardial biopsy (stage III) and blind antituberculous therapy (stage IV). In 32 patients (14%) a specific etiologic diagnosis was obtained (13 with neoplasia, 9 with tuberculosis, 4 with collagen vascular disease, 2 with toxoplasmosis, 2 with purulent pericarditis and 2 with viral pericarditis). "Diagnostic" pericardiocentesis (32 patients) was performed when clinical activity and effusion persisted for longer than 1 week or when purulent pericarditis was suspected, whereas "therapeutic" pericardiocentesis (44 patients) was performed to treat tamponade; their diagnostic yield was 6% and 29%, respectively. "Diagnostic" biopsy (20 patients) was carried out when illness persisted for longer than 3 weeks, whereas "therapeutic" biopsy was performed whenever pericardiocentesis failed to relieve tamponade; their diagnostic yield was 5% and 54%, respectively. The diagnostic yield difference between "diagnostic" and "therapeutic" procedures was significant ($p < 0.001$); in contrast, the global diagnostic yield of pericardiocentesis (19%) and biopsy (22%) was similar. At the end of follow-up (1 to 76 months, mean 31 ± 20), no patient in whom a diagnosis of idiopathic pericarditis had been made showed signs of pericardial disease. It is concluded that a "diagnostic" procedure is not warranted as a routine method, a choice between "therapeutic" pericardiocentesis and biopsy is circumstantial and must be individualized, and only through a systematic approach can a substantial diagnostic yield be reached in primary acute pericardial disease.

(Am J Cardiol 1985;56:623–630)

Clinical and pathologic features of acute pericardial disease have been known for many years.[1–3] By contrast, the approach to the etiologic diagnosis in several pericardial syndromes is not well established. The most frequently disquieting dilemma for the clinical cardiologist is the patient with acute pericardial disease without an apparent cause (primary acute pericardial disease). Most patients have self-limited clinical features and do not constitute a major problem of management, despite an unrecognized cause in most cases; however, in many patients the illness is not self-limited, and in many of such patients even an extensive workup is likely to result in negative etiologic conclusions. The possibility of life-threatening, treatable disease makes etiologic diagnosis a very important issue. In particular, tuberculous pericarditis is sometimes a very difficult diagnosis, and its early identification is necessary for successful treatment. This situation may easily lead to a useless, long-term antituberculous therapy; it is made worse by the controversial indications[4,5] for pericardiocentesis and open pericardial drainage with biopsy. Dispute has mainly been based on the risk and therapeutic value of closed needle pericardiocentesis compared with surgical drainage, with less emphasis on the diagnostic capabilities of both procedures. General agreement as to the safest and most sensitive approach to the etiologic diagnosis of acute pericardial disease is not found in published reports; in fact, attempts to analyze this common clinical problem are surprisingly scarce.[6] We believe that some clarification can be provided by the prospective application of a systematic study in a large group of patients with primary acute pericarditis and cardiac tamponade.

From the Servicio de Cardiologia, Departamento de Medicina, Ciudad Sanitaria "Vall d'Hebron", Barcelona, Spain. Manuscript received February 14, 1985; revised manuscript received May 13, 1985, accepted May 15, 1985.

Address for reprints: G. Permanyer-Miralda, MD, Servicio de Cardiologia, Ciudad Sanitaria "Vall d'Hebron", Paseo Valle de Hebron, s/n 08035 Barcelona, Spain.

Methods

The present study is composed of 231 consecutive patients (176 males, 55 females, aged 8 to 85 years, mean 41) who were

TABLE I Stage I: Diagnostic Yield

Type Pericarditis	No.
Tuberculous	4
Viral	2
Rheumatic	2

* Systemic lupus erythematosus (1 case); hypereosinophilic syndrome associated to Churg-Strauss vasculitis (1 case).

admitted to the Cardiology Service from January 1977 to October 1983 with acute pericarditis or cardiac tamponade or both. Patients with postinfarction or postpericardiotomy syndromes, chronic pericardial effusion or chronic constrictive pericarditis were not included in the study. Patients with pericarditis associated with renal failure, known neoplastic disease, trauma or radiation were not included. Acute pericarditis was diagnosed when at least 2 of the following criteria were present: characteristic chest pain, pericardial friction rub, and serial repolarization changes on the electrocardiogram. Cardiac tamponade was diagnosed when there were clinical signs of venous hypertension or paradoxical pulse (inspiratory decrease of arterial pressure >10 mm Hg)[7] associated with echocardiographic evidence of pericardial effusion in the absence of any other form of heart disease.

Study protocol: All patients were prospectively studied according to the following study protocol (Fig. 1).

Stage I—general studies and echocardiogram: In this stage, the following studies were carried out: complete clinical history, physical examination, electrocardiography, chest x-ray film, rheumatoid factor, specific serologic test for toxoplasmosis (immunofluorescent antibodies), tuberculin skin test (purified protein derivative 10 μ) and virologic studies (viral cultures in pharyngeal swabs and feces). In patients with tamponade, suspicion of pericardial effusion or illness lasting for more than 1 week, the following investigations were performed: echocardiography, tubercle bacilli investigation in 3 samples of sputum or gastric aspirate, blood culture, agglutinin titer against *Brucella melitensis*, and antinuclear antibody determination. In addition, any other routine study suggested by the initial examination was performed.

Stage II—pericardiocentesis: Pericardiocentesis was performed under the following circumstances: (1) cardiac tamponade, (2) clinical suspicion of purulent pericarditis, and (3) illness lasting for more than 1 week, with echocardiographic evidence of anterior and posterior pericardial effusion. In this study, pericardiocentesis was considered "therapeutic" if it was performed after the first indication; it was considered "diagnostic" if it was performed for the other 2 indications.

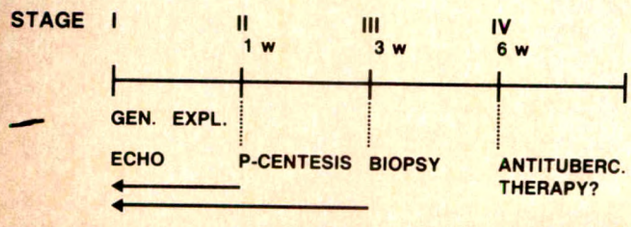

FIGURE 1. Study protocol. The protocol consists of 4 stages at different intervals. "Diagnostic" pericardiocentesis (P-CENTESIS) and biopsy are scheduled at 1 and 3 weeks (w), respectively, after hospital admission. "Therapeutic" procedures can be carried out at any time of the clinical evolution (**arrows**).

Pericardiocentesis was carried out either through subxiphoid or intercostal approaches. The following studies were carried out in the pericardial fluid: packed red cell volume, total proteins, lactic acid dehydrogenase, culture in ordinary and Löwenstein media, viral studies (culture in cellular lines HEP 2 and VERO, and in fibroblasts of human embryo lung), direct search for tubercle bacilli (Ziehl-Nielsen stain) and cytologic examination. When quickly relapsing or grossly hemorrhagic pericardial effusion was observed, the appropriate studies to rule out neoplastic disease were instituted.

Stage III—surgical biopsy of the pericardium: Pericardial biopsy was performed under 2 circumstances: (1) as a part of a therapeutic procedure (surgical drainage) in patients with severe tamponade relapsing after pericardiocentesis ("therapeutic" biopsy), and as a diagnostic procedure ("diagnostic" biopsy) in patients with an illness more than 3 weeks in duration after hospital admission and without etiologic diagnosis having been reached by previous procedures. Pericardial biopsy was performed after 1 week of treatment with isoniazide (400 mg/day) and streptomycin (1 g/day); this treatment was discontinued 1 week after biopsy unless tuberculosis was demonstrated. Biopsy was carried out by the subxiphoid approach. Histologic and bacteriologic study of the biopsy specimen and study of the pericardial fluid (as previously described) were performed. Other studies to rule out neoplasia were also done.

Stage IV: If fever and pericardial effusion of unknown origin persisted for more than 5 to 6 weeks, and did not lead to tamponade or constriction, blind antituberculous treatment was considered.

Pericardiectomy: Pericardiectomy was performed under the following circumstances: evolution to constrictive pericarditis, persistence of tamponade after surgical drainage, and relapsing pericarditis with frequent and disabling episodes.

Treatment: Patients were treated only with bedrest and nonsteroidal antiinflammatory drugs unless a specific cause was found.

Follow-up: Patients were seen in the outpatient clinic at 3 months, 6 months, 1, 2 and 5 years after hospital discharge, or more often as indicated by clinical evolution. After 5 years, follow-up was interrupted in patients with normal findings.

Results

Stage I: Pericardial effusion was present by classic echocardiographic criteria[8] in 124 of 231 patients (54%). The diagnostic yield of this stage is listed in Table I. Tubercle bacilli were found in sputum (culture in Löwenstein medium) in 4 patients. In 2 of the 33 unselected patients in whom viral cultures were performed, Coxsackie B virus was isolated from pharyngeal swabs and feces. In 110 unselected patients, serologic studies for toxoplasmosis were performed; 2 patients had a characteristic immunofluorescent antibody curve or positive IgM antibody, which allowed a diagnosis of active toxoplasmosis; in the other 10 patients, an immunofluorescent antibody titer (100 IU or higher) was found, but no serial studies or search for IgM antibodies were performed, and therefore the diagnosis of active toxoplasmosis is doubtful. These 10 patients have been included in the group with acute idiopathic pericarditis.

Stage II: Eighty pericardiocenteses were performed in 76 patients (Table II). In 9 patients (12%), pericardiocentesis was unproductive; only 1 major complication was observed (hemopericardium secondary to right

ventricular laceration, needing surgical treatment with uneventful recovery).

"Diagnostic" pericardiocentesis was performed in 32 patients (in 31 for illness longer than 1 week and in 1 for suspicion of purulent pericarditis). In 2 patients, positive diagnostic data were obtained: positive culture for tubercle bacilli and purulent exudate, respectively. The only false-negative diagnosis corresponded to a patient in whom lymph node biopsy specimen and subsequent pericardiectomy revealed tuberculosis.

"Therapeutic" pericardiocentesis was performed in 44 patients. Diagnostic data were obtained in 13 patients: neoplastic cells (9 cases), positive culture for tubercle bacilli (2 cases), purulent exudate (1 case), and hypereosinophilic exudate (1 case). Three of the 31 negative results were false-negative; in subsequent studies they were shown to correspond to tuberculous pericarditis (1 case) and neoplastic pericarditis (2 cases: cardiac angiosarcoma and metastasic carcinoma, respectively). One patient had a positive culture for tubercle bacilli, but a diagnosis of neoplasia had been made in the cytologic examination of the effusion; this latter finding is considered to be a false-positive diagnosis for purposes of specificity calculation.

In this stage, an etiologic diagnosis could be established in 15 patients (Table III), although in 2 of them (1 with hypereosinophilic syndrome and 1 with lymphoma) it had been already made in stage I; consequently, in stage II 13 new true-positive diagnoses were made (Table IV). On the other hand, there were 4 false-negative diagnoses (2 patients with tuberculous and 2 with neoplastic pericarditis) and 1 false-positive diagnosis (neoplastic pericarditis being diagnosed by cytologic examination in a patient with tuberculous pericarditis). Sensitivity and specificity of pericardiocentesis were 79% and 98%, respectively.

The global diagnostic yield of pericardiocentesis was 19% (15 of 76 patients) (Fig. 2); however, "diagnostic" pericardiocentesis had only a diagnostic yield of 6% (2 patients), whereas the diagnostic yield of "therapeutic" pericardiocentesis was 29% (13 patients).

Stage III: Surgical pericardial drainage with biopsy was carried out in 31 patients (Table V). No complications were observed.

"Diagnostic" biopsy (20 patients): The only positive result (5%) was in a case of tuberculous pericarditis. One false-positive result was observed in a patient whose biopsy specimen was interpreted as metastatic adenocarcinoma, and who remained symptom-free and without evidence of pericardial disease or neoplasia 4 years afterward. One false-negative result was observed in a patient with gastric carcinoma.

"Therapeutic" biopsy (11 patients): "Therapeutic" biopsy yielded 6 positive diagnoses (54%): neoplastic

pericarditis (3 cases), purulent pericarditis (2 cases) and tuberculous pericarditis (1 case). A false-negative result was observed in 1 patient with cardiac angiosarcoma in whom diagnosis was made in a subsequent pericardiectomy.

On the whole, 7 true-positive diagnoses (Table VI) were made in stage III, but only 1 was a new diagnosis (Table IV). Sensitivity and specificity of pericardial biopsy were 78% and 95%, respectively. The global diagnostic yield of pericardial biopsy was 22% (7 of 31 patients); however, the yield of "therapeutic" biopsy was 54% and of "diagnostic" biopsy only 5% (Fig. 2).

The global diagnostic yield (Fig. 2) of "therapeutic" procedures (pericardiocentesis and biopsy) was 35% (19 true-positive diagnoses in 55 procedures), whereas diagnostic yield of "diagnostic" procedures was 6% (3 true-positive diagnoses in 52 procedures). The difference between both rates is statistically significant ($p < 0.001$).

Stage IV: No patient reached stage IV. Accordingly, in no patient was blind antituberculous chemotherapy instituted.

Pericardiectomy: Pericardiectomy was performed in 15 patients (as a result of constrictive pericarditis in 9). Pericardiectomy resulted in diagnostic data in 6 patients (Table VII). In 2 patients the diagnosis had not been previously made (Table IV). There was 1 false-positive diagnosis (1 patient with a pathologic diagnosis of neoplasia in whom absolutely uneventful long-term follow-up led to the diagnosis of idiopathic pericarditis) and 1 false-negative diagnosis (purulent pericarditis).

Invasive extracardiac procedures: In 3 patients, etiologic diagnosis was made by means of the following studies (1 case each): lymph node biopsy (squamous carcinoma), pleural biopsy (tuberculosis) and gastrointestinal study with subsequent operation (gastric adenocarcinoma).

In the whole series of 231 patients, invasive cardiac procedures were carried out in 79 (34%) ("invasive" group). One hundred twenty-six invasive procedures were performed (80 pericardiocenteses, 31 biopsies and 15 pericardiectomies); these procedures resulted in an etiologic diagnosis in 20 patients (25%). The etiologic diagnoses after completion of the studies are listed in Table VIII. A definite diagnosis was made in 32 patients (14% of the whole series); in 16 of the 32 patients (50%), the diagnosis was made only by means of invasive cardiac procedures.

Relative prevalence of tamponade and pericardial effusion in the different etiologies: The relative prevalence of pericardial effusion and tamponade in the different etiologic types of pericarditis are listed in Table IX. Forty-four patients had tamponade. Of these, 28 patients (64%) had acute idiopathic pericarditis, 11 had neoplastic pericarditis, 3 had tuberculous pericarditis, 1 patient had purulent pericarditis and 1 had pericarditis associated with hypereosinophilic syndrome.

Follow-up: The follow-up period ranged from 1 to 76 months (mean 31 ± 20). Twenty-three patients (10%) were lost to follow-up; in 9 others follow-up was incomplete. Therefore, incomplete follow-up data are available for 32 patients (13%). However, only 3 of these 32 patients belonged to the group that was "invasively" studied (79 patients); in the remaining 29 patients the clinical symptoms and effusion, when present, resolved within a short time. This group had no finding that suggested a specific cause was present in the protocol study performed during admission.

Clinical course: Eight patients died during follow-up (all with neoplastic pericarditis). In 7 patients, a subacute evolution to a classic form of constrictive pericarditis requiring pericardiectomy was observed (4 with tuberculous pericarditis, 2 with purulent pericarditis and 1 with neoplastic pericarditis). Five other patients (3 with idiopathic pericarditis, 1 with tuberculous pericarditis and 1 with neoplastic pericarditis) developed effusive-constrictive pericarditis, and 2 of these (1 with tuberculous pericarditis and 1 with idiopathic pericarditis) required pericardiectomy. Therefore, in 203 patients with idiopathic, viral and toxoplasmic pericarditis, only 1 patient (with effusive-constrictive

pericarditis) required pericardiectomy, whereas 8 of the 24 patients with tuberculous, neoplastic and purulent pericarditis required it. In the last clinical examination none of the remaining patients with a diagnosis of acute idiopathic, viral or toxoplasmic pericarditis had died or had signs of constrictive pericarditis or another significant clinical condition.

Discussion

The problem of primary pericardial disease: Often, the etiologic diagnosis of pericardial disease is carried out according to the principle of "guilt by association."[9] This is the case when pericardial disease can be related to an associated condition, such as myocardial infarction, uremia or other known systemic disease. Even in these cases, the etiologic diagnosis may not be a straightforward matter. In addition, not infrequently the clinician is faced with the problem of recognizing severe, treatable disease in patients without noncardiac clues to the etiologic diagnosis. These instances may be labeled, on clinical grounds, primary pericardial disease. Frequently, the clinical features (acute onset with characteristic chest pain, absent or small effusion and quickly self-limited illness) are strongly indicative of acute idiopathic or viral pericarditis; not infrequently, however, idiopathic pericarditis shows less distinctive features, and its recognition from more severe and treatable conditions, such as tuberculosis or neoplasia, may be very difficult.[6,10,11] The occurrence of large or bloody effusions, cardiac tamponade or a clinical course over several weeks may make the etiologic diagnosis of pericarditis a difficult clinical dilemma, leading in some cases to the prescription of antituberculous therapy based on indirect diagnostic criteria.[12,13] Although considerable information about the usefulness of pericardiocentesis,[4–6,14] pericardial biopsy[4–6,13,15–18] or pericardiectomy[6,19] for etiologic diagnosis is available in published reports, comprehensive series on the value of an integrated approach to acute primary pericardial disease are lacking.

Limited etiologic value of clinical features: In the present series, clinical features of patients with tamponade or persisting effusion were of limited value for the etiologic diagnosis in the individual case. For instance, a long-standing, torpid clinical course has been considered suggestive of tuberculous pericarditis; however, in the present series, less than 2 weeks of evolution was present before admission in 4 of 9 patients. The presence of effusion, development of tamponade, hemopericardium and positive tuberculin skin test, although more common in some specific types of pericarditis, were prevalent enough in idiopathic cases to reduce their diagnostic usefulness in a particular patient. In fact, tamponade was relatively frequent (28%) in patients with acute idiopathic pericarditis with effusion, in contrast to previously reported data.[20] Moreover, the tuberculin skin test was not a reliable indicator of tuberculous pericarditis; in the present series it was negative in 3 of 9 patients with the latter condition, a similar prevalence as in the series of Fowler and Manitsas[17] but much lower than in the series by Rooney et al[13]; in contrast, it was positive in 41% of the tested patients with acute idiopathic pericarditis. However, grossly bloody pericardial effusion, although more frequent in neoplastic pericarditis (7 of 12 patients with effusion), was also seen in patients with acute idiopathic pericarditis, with a prevalence of 7 of 46 cases (in agreement with other series[6]). Even the combination of tamponade and hemopericardium was not by itself indicative of a particular cause; this combination was seen in 3 patients with acute idiopathic pericarditis.

Diagnostic yield of the present protocol: Thirty-two etiologic diagnoses (13%) were confirmed in the present series. This is not a strikingly low proportion considering the type of patients included in the present series. Regarding the methods that led to the etiologic diagnosis, these 32 patients are distributed as follows: (1) In 50% the cause was discovered only by invasive cardiac procedures (pericardiocentesis, pericardial biopsy or pericardiectomy). (2) In 37%, noncardiac studies disclosed the cause. (3) In 12%, the diagnosis was made both by noncardiac and invasive cardiac studies. The predominance of invasive diagnoses may be partially influenced by the failure to perform an objective diagnosis of viral or toxoplasmic pericarditis in cases in which this might have been done; however, our figures probably serve as an index of the proportion of diagnoses to be expected from cardiac and noncardiac studies as far as neoplastic, tuberculous and purulent pericarditis are concerned.

Diagnostic value of pericardiocentesis: Sensitivity and specificity of pericardiocentesis were high (79% and 98%, respectively), but diagnostic yield was markedly different, depending on whether pericardiocentesis was "diagnostic" (6%) or "therapeutic" (29%). The lower sensitivity of pericardiocentesis was related to its inability to demonstrate tuberculosis and neoplasia in 2 patients each. This shortcoming has been known for

many years.[6,10,17,21,22] The 9 patients with nonproductive pericardiocentesis did not bias the results in the "diagnostic" group, as only 1 of them (a patient with false-positive echocardiographic evidence of effusion) was discovered by subsequent studies to have neoplastic pericarditis, whereas the remaining 8 patients recovered uneventfully to the last follow-up control. In a similar way, hypothetical false-negative results seem to be virtually ruled out by subsequently adequate follow-up. In the case of tuberculous pericarditis (9 cases), pericardiocentesis did not prove very useful: In 2 of the 5 patients in whom it was performed, tubercle bacilli failed to be identified in pericardial fluid at all, whereas in the 3 patients from whom bacilli were recovered, identification was by growth in Löwenstein medium in all 3. Identification in all 5 was not by direct examination with the Ziehl-Nielsen stain, possibly because of a few bacilli in the fluid. This meant a delay of several weeks during which diagnosis was made by other procedures in 1 case. This limitation of pericardiocentesis in the diagnosis of tuberculous pericarditis has also been pointed previously.[11,13] In patients with neoplastic pericarditis, pericardiocentesis was more consistently useful than in tuberculosis, a diagnosis being obtained in 9 of 13 cases. However, pericardiocentesis failed to discover neoplastic cells in 2 patients; the occurrence of false-negative results in neoplastic pericarditis is well documented.[6,21,22]

Diagnostic value of pericardial biopsy: Pericardial biopsy as well as pericardiocentesis were of limited value in our patients in the absence of tamponade. The sensitivity and specificity of pericardial biopsy (78% and 95%, respectively) are almost the same as those of pericardiocentesis; similarly, its diagnostic yield was 5% (only 1 case) in "diagnostic" indications and 54% in "therapeutic" indications. Therefore, there appear to be good reasons for advising against biopsy, as well as against pericardiocentesis, when it is carried out only for diagnostic purposes. Limitations of pericardial biopsy lie mainly in its lower sensitivity in diseases with patchy pericardial involvement (especially neoplastic pericarditis,[6,23,24] where biopsy specimens in our series were negative in 2 of 6 patients) and in the possibility of false-positive diagnoses of neoplasia in cases of mesothelial hyperplasia.[25] Moreover, in all 5 cases of tuberculous pericarditis in which the pericardium was histologically examined either by biopsy or by pericardiectomy, the diagnosis was confirmed.

Diagnostic and therapeutic procedures: A striking result in our series is the very low rate of diagnoses made by "diagnostic" procedures (6%) compared with "therapeutic" procedures in which etiologic data were obtained in 35% of patients (Fig. 2). Accordingly, the distinction between "diagnostic" and "therapeutic" procedures is meaningful for clinical purposes. We believe that the major reason for this discrepancy is the high prevalence of cardiac tamponade in patients with neoplastic, tuberculous or purulent pericarditis (which are easily identified by the investigations performed in this protocol), compared with its lower prevalence in patients with pericarditis of other causes (68% vs 28% in patients with effusion). This difference was statistically significant ($p < 0.001$). The different prevalence rates of tamponade in both etiologic categories has been pointed out in retrospective series.[6,14,26] However, no definite guidelines for the indications of pericardiocentesis and biopsy have been established on the basis of this difference.

Diagnostic accuracy is a common issue in any etiologic study. How many objective diagnoses may have been missed by our protocol? The rather low diagnostic yield of stage I (6%) suggests that a number of pericarditides of viral or toxoplasmic origin may not have been identified. Despite the intrinsic difficulties in the diagnosis of viral pericarditis,[27,28] a more systematic use of the studies in stage I may increase the rate of these diagnoses in primary acute pericardial disease. On the contrary, we contend that the strict performance of the protocol allowed the identification of almost all cases of severe and treatable diseases such as tuberculous, purulent or neoplastic pericarditis. Indirect evidence of this assumption is provided by the fact that no patient in whom the invasive procedures failed to identify the cause, had signs of active pericardial or systemic disease at the end of follow-up; moreover, clinical cure had been spontaneously achieved in all but 1 patient in whom subacute effusive-constrictive pericarditis had developed, and in whom pericardiocentesis, biopsy and pericardiectomy had not yielded the diagnosis. Although the possibility of self-limited tuberculous pericarditis has been recognized,[9] it appears to have been an exceptional occurrence in a disease in which classic reports[9,29] point to an unfavorable evolution in almost all cases; therefore, the finding of a good evolution in our cases with negative etiologic investigations appears relevant for clinical practice. The strikingly different pattern of evolution to constrictive pericarditis in patients with tuberculous, neoplastic and purulent disease on the one hand, and in those with idiopathic disease on the other hand (although already known[30]), is also suggestive of a correct etiologic categorization of the latter group.

Choice between pericardiocentesis and pericardial biopsy: Although our global diagnostic yield of pericardiocentesis (19%) and biopsy (22%) was similar, there are qualitative differences between both procedures: (1) Whereas biopsy is more cumbersome and may entail the need for general anesthesia, the risk of undesirable accidents is lower than with pericardiocentesis; therefore, the risk/benefit ratio should be lower than with the latter procedure.[31] (2) Direct histologic examination of the pericardium may allow almost immediate diagnosis in cases of tuberculosis, avoiding the delay inherent in culturing tubercle bacilli. (3) The procedure may allow a direct visualization of the pericardium and, in addition, a quicker and more complete removal of fluid. The choice between "therapeutic" pericardiocentesis and "therapeutic" biopsy may rest on several circumstances such as skill of the cardiologist, availability of a cardiac surgeon, operating-room facilities, severity of hemodynamic impairment, and so on. However, there may be advantages in both approaches. For instance, in the present series, if an emergency surgical drainage had been performed in the 44 patients

undergoing a "therapeutic" pericardiocentesis, 19 subsequent surgical procedures might not have been performed. It can be argued that with needle pericardiocentesis as the selected procedure, in 26 patients this was all that was needed for their correct management without any surgical procedure in the entire course of the disease. The choice, therefore, is circumstantial and must be individualized. A discussion of the choice between both techniques in "diagnostic" indications seems pointless, as our results show little justification for "diagnostic" procedures (diagnostic yield 6%). However, in individual patients in whom severe clinical findings are present, despite the absence of tamponade, a "diagnostic" procedure may be justified. When purulent pericarditis is suspected, the usual clinical setting may make pericardiocentesis desirable. Also, in communities in which tuberculosis is highly prevalent, a "diagnostic" procedure could be advised in patients with persistent illness for more than 3 weeks; in these patients pericardial biopsy should be chosen (despite its global low diagnostic yield) because it is a safe, rapid procedure providing information from both pericardial tissue and fluid.

Spectrum of diagnosis in the present series: Several comments may be appropriate to the spectrum of etiologic diagnoses identified in our study.

Tuberculous pericarditis accounts for 4% of all diagnoses. This is a low prevalence rate in a community in which tuberculosis is still considered to be a significant cause of morbidity; such prevalence is still not high (7%) when only patients who need any invasive procedure are considered (6 of 79). However, considering that tuberculosis is a curable disease, these figures suggest a high enough prevalence to warrant investigation for tuberculosis in cases of pericarditis that are not rapidly self-limited.

Although they reflect a very low prevalence as the presenting feature of neoplasia, the 12 cases in which pericardial involvement was the first manifestation of extracardiac malignancy (5% of our series) constitute a remarkable finding, because it is the most common specific diagnosis in the present study. Although the clinical onset of neoplastic disease with cardiac tamponade is well known,[23,32,33] its prevalence in the whole spectrum of acute pericardial disease is not well documented. Our figures indicate the need of considering the possibility of extracardiac malignancy in cases of acute pericardial disease, most particularly those presenting as tamponade.

The prevalence of toxoplasmic pericarditis is not known.[34] The present series shows that it may not be negligible in some communities. Although it is unlikely that all cases with a high antitoxoplasma IgG titer (9% of all tested cases) correspond to true toxoplasmic pericarditis, the prevalence of the latter is likely to be higher than the 1.8% detected when only the cases with available IgM titer or subsequent IgG titer were analyzed; therefore, the true prevalence rate should lie between 1.8% and 9%. In only 4 patients (1.7% of our series) was a collagen vascular disease identified, in agreement with the notion that isolated pericarditis is rarely the presenting feature of this disease group.[35]

The very low prevalence rate of purulent pericarditis (0.8%) reflects the rarity of this disorder in the absence of risk factors,[36] such as thoracic surgery or immunosuppression, which were not present in the patients included in this study. The true prevalence of viral pericarditis is not known because of the difficulties in its objective diagnosis.[27,28] In fact, isolation of a virus from a pharyngeal swab or from the feces is not sufficient evidence for an unquestionable diagnosis of viral pericarditis. Despite extensive study, by far the most prevalent diagnosis in our series was acute idiopathic pericarditis (86%). We believe that if a significant reduction of this figure is to be realized, a wide range of routine sophisticated virologic and serologic studies should be carried out, with a dubious cost/efficacy ratio for clinical purposes.

Limitations: Considering that with invasive procedures an etiologic diagnosis was achieved in only 20 of 79 patients (25%), the present study could be considered too aggressive, because 36 patients underwent more than 1 invasive procedure, and, moreover, only 1 new diagnosis was made in stage III. These data suggest that it may be advisable to simplify the protocol by unifying stages II and III, and by limiting "diagnostic" procedures. If only "therapeutic" procedures had been applied, the rate of diagnostic results would have been 35%. However, caution must be used when limiting invasive procedures, because we contend that a judicious use of them is justified by 2 considerations: (1) Owing to the strict use of our protocol, in virtually no patient was the diagnosis of tuberculous, neoplastic or purulent pericarditis missed; and (2) at no time was blind antituberculous therapy required, because etiologic information from stages I to III was sufficient to rule out tuberculosis (the single most prevalent curable disease), no patient having reached stage IV.

Clinical implications: (1) "Diagnostic" pericardiocentesis as a routine method is not warranted in the management of acute pericardial disease, except if there is a clinical suspicion of purulent pericarditis. (2) A "diagnostic" procedure is only indicated in individual patients, such as in patients with illness longer than 3 weeks, and belonging to a community with high prevalence of tuberculosis; in these few instances, pericardial biopsy should be chosen because it is safe and provides information from both pericardial tissue and fluid. (3) The choice between "therapeutic" pericardiocentesis and "therapeutic" biopsy must be considered on an individual basis. (4) Although some parts of the present protocol may be controversial, we believe that only through a systematic approach can a substantial diagnostic yield be reached in patients with primary acute pericardial disease.

Acknowledgment: We are indebted to David H. Spodick, MD, for his invaluable criticism and encouragement.

Post–Cardiac Injury Syndrome and an Increased Humoral Immune Response Against the Major Contractile Proteins (Actin and Myosin)

IVAN DE SCHEERDER, MD, JOEL VANDEKERCKHOVE, PhD, JOHAN ROBBRECHT, MD, LUC ALGOED, MARC DE BUYZERE, JORIS DE LANGHE, MD, GUIDO DE SCHRIJVER, MD, and DENIS CLEMENT, MD, PhD

To better understand the pathogenesis of the post–cardiac injury syndrome (PCIS) 2 models of cardiac injury were studied. One hundred twenty-nine patients who underwent cardiac surgery and 80 patients with acute myocardial infarction (AMI) were prospectively followed and the levels of anti-heart antibodies (AHA), anti-actin antibodies (AAA) and anti-myosin antibodies (AMA) were determined. In the surgical group, PCIS developed in 27 patients (21%) and incomplete PCIS in 36 (28%). In the AMI group, PCIS did not develop in any patient, but incomplete PCIS developed in 11 patients (14%) ($p < 0.001$). The surgical group showed a significantly higher humoral immune response than the AMI group when analyzed for AHA and anti-contractile protein antibodies. After cardiac surgery, AHA developed in 59 patients (46%), AAA developed in 33 (26%) and AMA developed in 49 (38%); in the AMI group, significant levels of AHA, AAA and AMA developed in 16 (20%), 7 (9%) and 13 patients (16%), respectively. These studies show a significant correlation between the PCIS clinical classification and auto-antibodies raised against heart contractile proteins.

(Am J Cardiol 1985;56:631–633)

The postpericardiotomy syndrome is a frequent complication after cardiac surgery.[1–6] It is characterized by the persistence or occurrence of fever, leucocytosis and signs of pericardial and often pleural reaction, frequently with effusion and pneumonitis after the first postoperative week. Dressler et al[7,8] described a similar illness, the post–acute myocardial infarction (AMI) syndrome. The prevalence varies from 0 to 6% of cases with AMI in different studies.[8–14] Since other forms of cardiac injury give rise to a similar complication, this syndrome is now generally referred to as post–cardiac injury syndrome (PCIS).[15] Although these syndromes are strikingly similar and have been well defined clinically, their pathogenesis remains unclear. The clinical observation that these syndromes appear 7 or more days after the acute injury and are sensitive to corticosteroid therapy suggests that immunologic factors are involved in the pathogenesis. The finding of anti-heart antibodies (AHA)[2–5] and circulating immune complexes[16,17] in sera of most of these patients supports this view.

AHA have been determined by an indirect immunofluorescence technique and different patterns have been described.[5,18] We have shown that antibodies producing a cross-striated pattern in heart tissue are mainly directed against the major contractile proteins, actin and myosin.[19]

The present study compares clinical events following 2 important models of cardiac injury (cardiac surgery and AMI) and determines serially humoral immune response against myocardial muscle cells and especially against the major contractile proteins, actin and myosin.

Methods

The cardiac surgery group consisted of 129 adult patients (26 women, 103 men), aged 43 to 70 years (mean 57). Nineteen patients had undergone aortic valve replacement, 14 mitral valve replacement, 10 combined valve replacement and 86 aorto coronary bypass procedures. The AMI group consisted of 80 patients (15 women, 65 men), aged 42 to 86 years (mean 64).

Patients were grouped according to the degree of PCIS: (1) those who fulfilled the 3 classic features of the PCIS after the first post-injury week—fever, pericarditis and laboratory evidence for inflammation (complete PCIS); (2) those who fulfilled 2 of the main features (incomplete PCIS); and (3) those who showed only 1 or none of the main features (no PCIS).

Serum samples were collected before surgery and 1 to 60 days after operation or after AMI. Sera from 40 patients without obvious cardiovascular disturbances, matched for sex and age, were used as controls. All sera were stored at −20°C and analyzed within 10 months.

TABLE I Occurrence of Post-Cardiac Injury Syndrome (PCIS) in the Two Study Populations: Clinical Classification

	Cardiotomy (n = 129)	Infarction (n = 80)	p*
PCIS	27 (21%)	0 (0%)	
Incomplete PCIS	36 (28%)	11 (14%)	<0.001
No PCIS	66 (51%)	69 (86%)	

* Chi-square analysis comparing the incidence of PCIS, incomplete PCIS and no PCIS after cardiotomy and infarction.

TABLE II Occurrence of Anti-Heart Antibodies (AHA), Anti-Actin Antibodies (AAA) and Anti-Myosin Antibodies (AMA) After Cardiotomy and Acute Myocardial Infarction

	Cardiotomy	Infarction	p*
AHA	59 (46%)	16 (20%)	<0.001
AAA	33 (26%)	7 (9%)	<0.005
AMA	49 (38%)	13 (16%)	<0.002

* Chi-square analysis comparing the incidence of AHA, AAA and AMA after cardiotomy and infarction.

Anti-heart antibodies: The indirect immunofluorescence technique of Coons and Kaplan[20] was used. Monkey heart muscle, frozen in liquid nitrogen, was cut into sections 4 μm thick in a cryostat at −20°C, mounted on slides and incubated for 20 minutes with 1/10 diluted test serum to be investigated. Four patterns of immunofluorescence staining were distinguished: cross-striated, diffuse intracellular, intercalated disc and heart muscle membrane fluorescence. In this study we concentrated on the cross-striated fluorescence pattern. The intensity of fluorescence staining was graded 0 to +4; only fluorescence of grade +2 or higher was considered positive in this study.

Anti-actin and anti-myosin antibodies: The indirect enzyme-linked immunosorbent assay was used for the quantitation of anti-actin autoantibodies (AAA) and anti-myosin autoantibodies (AMA).[21] The conjugate used for the assay was alkaline phosphatase conjugated goat anti-human IgG (Sigma Chemicals). Rabbit muscle heavy meromyosin (HMM, Sigma) and bovine cardiac actin, prepared according to the method of Spudich and Watt[22] were coated overnight at 4°C onto glutaraldehyde coated immunobeads (Plastic Ball Co.). Sera were added in dilutions of 1/10 to 1/100000 and incubated at 37°C for 2 hours. After washing, the amount of enzyme bound was assayed using N-nitrophenyl phosphate disodium (Sigma Chemicals) as substrate. The reaction was terminated by the addition of 1 N Na OH. The absorbance of test beads was measured on a Vitatron spectrophotometer at a wavelength of 410 nm. Samples that exceeded the mean value of the control group by 2 standard deviations were considered as positives in this study.

Statistics: The significance of differences between incidences was evaluated by the chi-square test.

Results

Post-cardiac injury syndrome: Following our clinical classification, we found that in the surgical group PCIS developed in 27 patients (21%) and incomplete PCIS in 36 (28%) (Table I). The AMI group had a lower complication rate of PCIS; no patient in this group showed complete PCIS and only 11 patients (14%) showed incomplete PCIS.

Correlation between the PCIS clinical classification and the level of anti-contractile protein autoantibodies: The results summarized in Table II indicate that AHA, AMA and AAA are found significantly more often after cardiotomy than after AMI. Quantitative analysis (Table III) showed a direct correlation between the intensity of PCIS and the titer of

antibodies as determined either by the indirect immunofluorescence technique using frozen sections of heart tissue or by the ELISA technique using actin and/or myosin as antigens.

This is illustrated by the fact that in each group analyzed, the highest intensity of PCIS correlates well with the highest frequency of high titer antisera (e.g., 7 high level AHA [>4] were only found in the group with complete PCIS). Similar results were obtained when searching for AAA or AMA. Generally higher antibody titers were observed when myosin was used as antigen than actin.

Discussion

In this report we have studied 2 models of cardiac injury (cardiac surgery and AMI) both at the level of the PCIS and at the level of auto-antibodies directed against heart tissue and its major contractile proteins, actin and myosin. In agreement with previous studies[3–5,8–14] PCIS was found significantly more frequently and at significantly higher levels in patients who had undergone cardiac surgery than in patients with AMI. In correlation with these clinical results, the immune response was significantly more important after cardiac surgery than after AMI, and a clear correlation was observed between PCIS clinical classification and the levels of specific auto-antibodies against actin and myosin.

Myocardial injury during operation or during AMI is accompanied by the release of cellular proteins or protein-complexes that may function as auto-antigens leading to the formation of what has been referred to as AHA. Actin and myosin are the major constituents of the heart cellular proteins, and thus are likely to be good candidates to trigger the immune response. It has been shown[19] that auto-antibodies generated after cardiotomy, giving a cross-striated fluorescence pattern, are mainly directed against the major contractile proteins, actin and myosin. Cardiac surgery led more frequently to both higher levels of auto-antibodies against actin and myosin and more frequently to PCIS than AMI, although the latter normally gives rise to a more important myocardial damage. Apparently, cardiac surgery is more immunostimulating than infarction. This may be because: (1) Viral infection may, occur during surgery and trigger the immune response.[23,24] (2) The exposure to air or to chemicals (disinfectants) of cardiac tissue may denature a fraction of the released proteins so that they become more immunogenic than the native molecules. (3) The action of anesthetic agents may change immune response. (4) Antigens are massively released in a short period of time during cardiac surgery, whereas after AMI antigens may be released more slowly and during a longer period.

Consistently higher levels of auto-antibodies against myosin than against actin were found. This may be explained by the higher antigenicity of myosin but also by the fact that actin is known to form stable complexes with at least 2 known serum constituents—the vitamin D binding protein[25] and serum gelsolin[26]—so that it may become less immunogenic.

Our studies reveal a good correlation between the release of typical major heart muscle antigens, the corresponding immune response and the concomitant inflammatory reaction. However, further investigations are necessary to detect additional interfering factors and to see if this phenomenon may be generalized to other diseases associated with important cell death.

Acknowledgment: We thank M. Puype, A. Vermarcke and the technicians of the Red Cross Blood Center for the excellent technical help, the nurses and technicians of the departments of cardiology, surgery, virology and the Red Cross Blood Center for collecting the blood samples.

Cardiovascular Deconditioning Produced by 20 Hours of Bedrest with Head-Down Tilt (−5°) in Middle-Aged Healthy Men

F. ANDREW GAFFNEY, MD, J.V. NIXON, MD, ERLING S. KARLSSON, MD, WILLIAM CAMPBELL, MD, A.B.C. DOWDEY, MD, and C. GUNNAR BLOMQVIST, MD

Cardiovascular deconditioning after prolonged bedrest has been attributed to inactivity. To examine the role of the altered distribution of body fluids, 5 healthy men, aged 41 to 48 years, were studied before, during and after a 20-hour period of bedrest with head-down tilt (−5°). This intervention produces a marked central shift of intravascular and interstitial fluid, but the short duration minimizes the effects of inactivity. Central venous pressure, cardiac output and stroke volume all increased significantly ($p < 0.05$) from supine baseline mean values; central venous pressure from 8.6 to 12.6 cm H_2O, cardiac output from 6.9 to 7.9 liters/min, and stroke volume from 104 to 113 ml after 15 minutes of tilt, but all values returned to baseline within 20 hours. Supine central venous pressure after tilt was 7.4 cm H_2O, cardiac output 5.7 liters/min and stroke volume 84 ml. Blood volume decreased 0.51 liters. After tilt, orthostatic stress produced a higher heart rate (90 ± 18 vs 68 ± 12 beats/min). Maximal oxygen consumption decreased (2.36 ± 0.41 vs 2.62 ± 0.48 liters/min), mainly owing to reduced stroke volume (87 ± 22 vs 107 ± 18 ml, $p < 0.05$). Thus, tilt produced a transient increase in central venous pressure, stroke volume and cardiac output, but supine mean values were below baseline levels after 20 hours. The post-tilt state was qualitatively and quantitatively similar to that seen after 2 to 3 weeks of bedrest or several days of spaceflight. These results are also similar to those from a previously studied group of ten 20- to 30-year-old normal men. However, the increase in central venous pressure tended to be larger and of longer duration in the middle-aged group. Furthermore, in the young men the initial increase in stroke volume produced relative bradycardia, with no change in cardiac output and arterial pressure. Cardiac output increased in the middle-aged group, but arterial pressure was controlled by vasodilatation. Heart rate did not change. The results support the concept that cardiovascular deconditioning after bedrest is primarily an adaptation to a postural fluid shift rather than to inactivity. Age-related differences in hemodynamic responses to central fluid shifts appear to be present.

(Am J Cardiol 1985;56:634–638)

Prolonged bedrest causes cardiovascular deconditioning with orthostatic intolerance and decreased exercise capacity.[1–4] The mechanisms of these responses are unknown, but prolonged inactivity is generally believed to be a major factor. However, previous studies[5,6] in our laboratory in young healthy subjects have shown that a 24-hour period of bedrest with a 5° head-down tilt, introduced by Kakurin et al[7] as a means of simulating 0 gravity, produces the intravascular volume loss and cardiovascular deconditioning seen with 2 to 3 weeks of bedrest. These results suggest that an adaptation to a central fluid shift associated with the supine position, rather than inactivity per se, may be a major factor producing deconditioning after bedrest. The present study was performed to determine the extent and mechanisms of bedrest deconditioning in men comparable in age to symptomatic patients with acquired heart disease and to compare the responses to these middle-aged men with those of younger subjects studied previously.[5,6]

Methods

Subjects: Five sedentary men, 45 ± 3 years old (range 41 to 48), were recruited from the liberal arts faculty of a local university (Table I). None had participated in medical research previously, but volunteered on the basis of a notice posted on campus. These subjects were the first 5 who contacted our office.

Procedures: Procedures were reported in detail previously.[5,8] Briefly, indirect blood pressure was measured with a semiautomated cuff device (Narco Bio-systems Electro-

sphygmomanometer PE 300), heart rate by electrocardiogram (Frank X,Y,Z leads), forearm flow and venous compliance by venous occlusion plethysmography, leg volume during bedrest by measurements of leg circumferences and Simpson's rule, cardiac output by an acetylene rebreathing technique (coefficient of variation 4.3% over the range of 5 to 19 liters/min), blood volume by simultaneous measure of red cell mass (Cr^{51}) and plasma volume (radioiodinated serum albumin I^{131}) and plasma renin activity by radioimmunoassay. Exercise was performed upright on a mechanically braked bicycle ergometer (Monark) with progressive increases in workload every 4 minutes until maximal effort was achieved. Maximal oxygen consumption was defined as the level at which heart rate and oxygen consumption failed to increase despite an increased workload, and was measured by collection of expired air in a Douglas bag and analyzed by mass spectrometer and Tissot spirometer. Lower body negative pressure with 3 to 5 minutes at levels of −16, −32, −40 and −50 mm Hg was obtained with a device developed for use during the Skylab flights. The subjects were supine (0° tilt). Leg volume changes during lower body negative pressure were estimated by a double-stranded, mercury-in-silastic strain gauge placed around the calf at the level of its maximal girth. Central venous pressure was measured with a catheter inserted percutaneously and positioned fluoroscopically. The anterior and lateral chest walls were marked to provide 3-dimensional reference coordinates for positioning the pressure transducer.

Protocol: After the subjects gave informed written consent, a physical examination, complete blood count, SMA-12 and urinalysis were performed. Subject familiarization included tours of the laboratory and clinical research center and short periods of exercise (300 kpm for 6 minutes) and lower body negative pressure (−32 mm Hg). After at least 1 hour of rest, lower body negative pressure was repeated (−50 mm Hg) and a maximal bicycle stress test performed.

On the morning of the tilt procedure, the subject reported to the laboratory in a fasting state, where blood samples were drawn, a central venous pressure catheter was inserted and blood volume was measured. The subject was then ambulatory and ate a light breakfast. One to 3 hours later, lower body negative pressure (−50 mm Hg) was repeated. The subjects were again ambulatory for 1 to 2 hours until approximately 1 hour after lunch, when baseline measures were repeated. The 5° head-down tilt was begun within 30 minutes and continued for 20 hours. The subjects received a 4-g sodium diet and fluids ad lib. After the tilt period, baseline measurements were repeated with the subject supine (0°), during lower body negative pressure and sitting on the bicycle. The central venous pressure catheter was removed immediately before exercise.

Statistical analysis included paired t tests or repeated measures analysis of variance with Student-Newman-Keuls test for individual differences.[9] Occasional data points (<0.5%) for individual subjects were interpolated when measurement at a specific time was not available. All values are reported as the mean ± standard deviation. A significance level of $p \leq 0.05$ was used.

Results

All 5 subjects completed the bedrest study without complications, except 1 subject with marked vagotonia before the study. He had a brief period of asystole followed by bradycardia during the post-tilt lower body negative pressure stress and required intravenous atropine to restore normal sinus rhythm. None of the subjects complained of the nasal congestion or stuffiness frequently reported in head-down tilt or spaceflight, but minor musculoskeletal complaints were universal.

TABLE I Characteristics of the Five Study Subjects

Age (yr)	45 ± 3
Height (cm)	179 ± 6
Weight (kg)	88 ± 12.9
$\dot{V}O_2$ max (ml·kg^{-1}·min^{-1})	30 ± 6.1
Total blood volume (liters)	6.28 ± 0.30

Values are mean ± standard deviation.
$\dot{V}O_2$ max = maximal oxygen consumption.

The initial hemodynamic responses to the 5° head-down tilt were evident within 15 minutes (Fig. 1). Central venous pressure increased from 8.6 ± 2.7 cm H_2O to 12.6 ± 2.5 cm H_2O after 15 minutes of head-down tilt and was associated with an increase in stroke volume (from 104 ± 8 to 113 ±16 ml) and cardiac output (from 6.9 ± 1.4 vs 7.9 ± 1.4 liters/min) ($p \leq 0.05$). Heart rate, blood pressure and forearm blood flow had not changed significantly at this time. After 4 hours, central

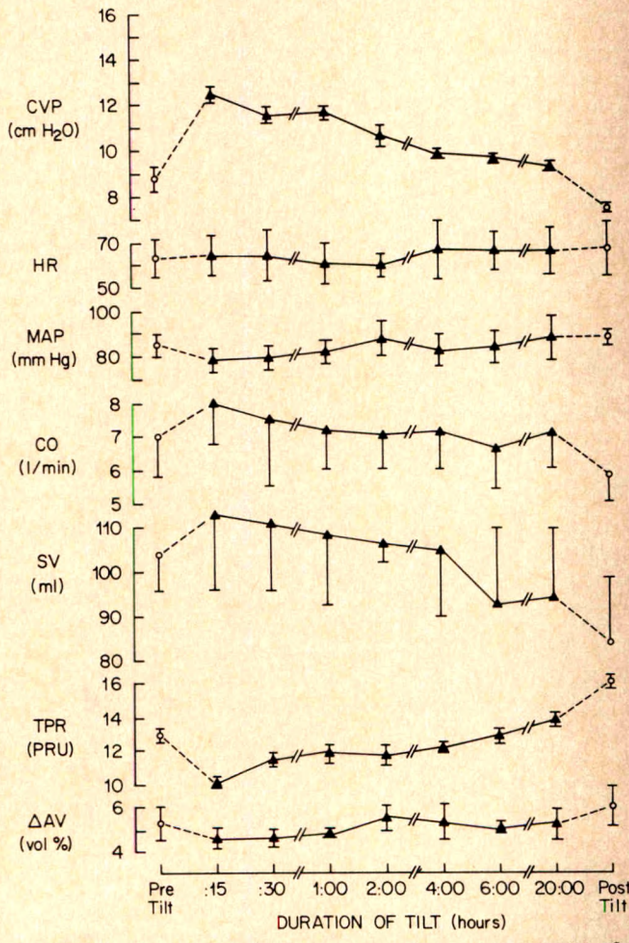

FIGURE 1. The hemodynamic responses to head-down tilt (−5°). Measurements before and after bedrest in the supine position were taken within 10 minutes of tilt. Stroke volume (SV) and central venous pressure (CVP) were significantly elevated by tilt and were significantly lower after tilt ($p < 0.05$). Values are mean ± standard deviation. ΔAV = calculated arteriovenous difference for oxygen; CO= cardiac output; HR = heart rate; MAP = mean arterial pressure; TPR = total peripheral resistance.

venous pressure was still elevated, but cardiac output and stroke volume returned almost to baseline values before tilt. Although central venous pressure was slightly elevated for the duration of the tilt, other measurements returned to pre-tilt levels by 4 to 6 hours. Leg volume decreased from 17.24 ± 2.51 to 16.96 ± 2.30 liters after 20 hours of bedrest.

During head-down tilt, peripheral venous hematocrit increased from 41.8 ± 1.5% to 44.2 ± 2.2% ($p < 0.04$). Urine output was 2.19 ± 0.30 ml/min during the first 6 hours of tilt, but only 1.55 ± 0.11 ml/min in the subsequent 10 hours. Hourly sodium excretion followed a similar pattern, 16.4 ± 3.3 vs 5.3 ± 1.5 mEq/hour in hours 0 to 6 and 7 to 16, respectively. Plasma renin activity decreased in the first 6 hours of tilt from (0.17 ± 0.02 vs 0.65 ± 0.20 $ng \cdot ml^{-1} \cdot min^{-1}$), but returned to baseline by 16 hours (0.42 ± 0.20 $ng \cdot ml^{-1} \cdot min^{-1}$). When the subjects resumed the supine position after tilt, central venous pressure (−14%), stroke volume (−19%) and cardiac output (−17%) were lower in all subjects ($p \leq 0.05$). The differences in stroke volume (−26%) and heart rate (+31%) were even greater when the subjects were sitting before exercise.

The tolerance to lower body negative pressure was decreased by the 20 hours of head-down tilt (Fig. 2). All subjects tolerated a −50-mm Hg level before tilt, but 4 were presyncopal at the −40-mm Hg level after tilt. Signs included lightheadedness, heart rate instability and paradoxical vasodilation. Central venous pressure decreased during lower body negative pressure before and after tilt to a similar degree and cardiac output was likewise maintained at an almost identical level compared with values before tilt; however, heart rate was substantially higher and stroke volume lower. Total peripheral resistance and mean arterial blood pressure did not differ at rest or at −16 mm Hg, but at maximal lower body negative pressure, tended to be slightly higher after tilt. Forearm blood flow was higher at rest and at −40 mm Hg lower body negative pressure after tilt (6.6 ± 2.2 to 5.9 ± 2.3 vs 4.4 ± 0.8 to 3.5 ± 0.8, ml/100 ml/min, rest and −40 lower body negative pressure, $p < 0.05$), while leg volume changes were not significantly different at −40 mm Hg lower body negative pressure.

A significant deconditioning effect was seen in all 5 subjects (Fig. 3). Although stroke volume fell by 19%, a slightly higher heart rate (169 ± 12 vs 164 ± 13 beats/min) and a wider atrioventricular oxygen difference (16.4 ± 2.7 vs 13.3 ± 2.3, vol%) resulted in a de-

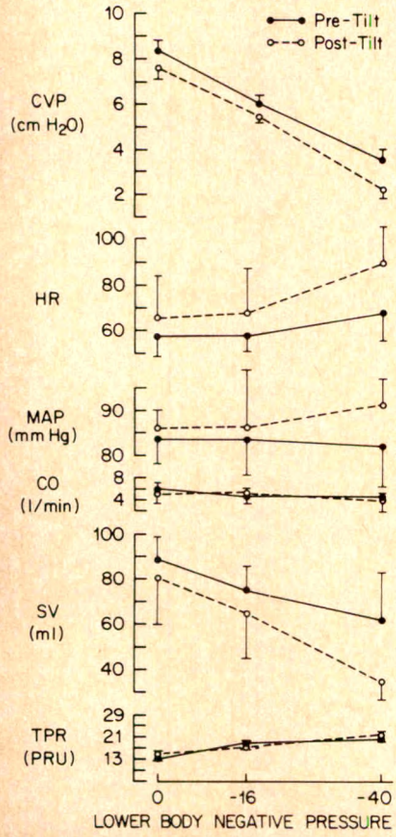

FIGURE 2. Response to lower body negative pressure before (**solid line**) and after (**dashed line**) a 20-hour period of bedrest with −5° head-down tilt. Abbreviations are as in Figure 1.

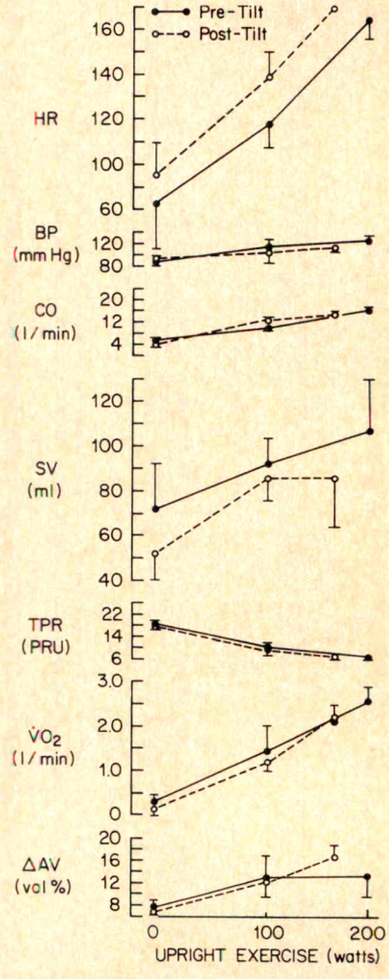

FIGURE 3. Responses to upright exercise before and after bedrest with −5° head-down tilt. Heart rate (HR) is significantly higher and stroke volume (SV) lower at maximal exercise after tilt ($p < 0.05$). BP = blood pressure; $\dot{V}O_2$ = oxygen consumption; other abbreviations as in Figure 1.

crease in maximal oxygen consumption of only 10%. Maximal cardiac output and mean arterial pressure both decreased while total peripheral resistance was unchanged.

Discussion

During and after head-down tilt, the hemodynamic and endocrine responses of this group of middle-aged men were qualitatively similar to those of younger subjects undergoing comparable periods of bedrest with head-down tilt.[5,6] However, increases in central venous pressure were somewhat greater and increases in stroke volume persisted somewhat longer in the middle-aged subjects. The older subjects increased cardiac output transiently during early tilt, but maintained a relatively constant arterial pressure with a substantial drop in total peripheral resistance. In contrast, in our younger subjects moderate bradycardia developed, which kept cardiac output and, therefore, blood pressure, constant. Corresponding age-related differences have been seen during orthostasis in hypovolemic symptomatic patients with mitral valve prolapse.[10] The older patients used vasoconstriction as a primary means of regulating blood pressure, whereas in younger patients tachycardia was more likely to develop. The results emphasize the fact that characterization of baroreflexes must include measures of peripheral resistance as well as heart rate.

The exact amount of fluid shifted into the central compartment with head-down tilt is not known, because both splanchnic and lower limb venous beds are involved and estimates of the former are difficult. The measured volume loss from the legs was approximately 300 ml. This finding is consistent with the data of Echt et al,[11] which would predict a central shift of at least 500 ml to produce comparable central venous pressure increases. Effective systemic venous compliance was not measured in these older subjects, but a prior study suggests that prolonged changes in effective systemic venous compliance are not an important response to bedrest.

Loss of salt and water with a decrease in intravascular and interstitial volume appear to be more important compensatory mechanisms. Sodium and water excretion over the first few hours of bedrest with head-down tilt increased to provide rapid readjustment of central venous pressure to pre-tilt levels. Our previous studies suggest that plasma renin, aldosterone and antidiuretic hormone levels are all reduced acutely and mediate diuresis.[5,6] Plasma renin activity showed a similar decrease in the present study.

Several lines of evidence argue against inactivity being the major cause of deconditioning after bedrest. First, this and previous studies of short periods of bedrest with head-down tilt[5,6] documented deconditioning in the absence of any prolonged inactivity. Myocardial and musculoskeletal adaptations to inactivity would be measured in days to weeks rather than the 20 hours of inactivity used in our studies. Second, exercise in the supine position during bedrest, with programs ranging from heavy dynamic exercise to static efforts,[12] generally fails to prevent the development of cardiovascular dysfunction. Several studies of supine exercise during bedrest, recently reviewed by Blomqvist and Stone,[4] showed little or no protection. Third, if inactivity is a major factor, physical training should accelerate recovery, but this was not found in a recent study by DeBusk et al.[13] These investigators postulated that the mere exposure to orthostatic stress was sufficient to overcome the deconditioning associated with bedrest. These data, combined with the fact that prolonged bedrest, head-down tilt, upright water immersion and spaceflight produce similar states of cardiovascular dysfunction, suggest that the primary cause is a response to an altered distribution of body fluids and intravascular pressures. The common denominator of these interventions is a cephalad fluid shift and a transient increase in cardiac filling pressure.[4]

Several mechanisms contribute to the orthostatic intolerance of bedrest-induced deconditioning. Decreased intravascular volume is a significant factor. In our subjects blood volume decreased 8%, a level comparable to that reported previously.[4,14,15] However, the response to an acute volume loss of this magnitude is less severe than the orthostatic intolerance produced by bedrest. Ekblom et al[16] measured maximal oxygen uptake in healthy young adults before and after phlebotomy of 800 ml of whole blood. Although this reduced hemoglobin concentrations by almost 13%, maximal oxygen consumption decreased by only 6%. Similar results were obtained by Saltin,[17] who examined work capacity in normal subjects before and after heat-induced dehydration. Our subjects had a larger decrease in maximal oxygen consumption despite smaller changes in blood volume. In addition, attempts to rehydrate subjects after bedrest or to prevent the blood volume loss have not corrected the deconditioning. Neither direct infusion of normal saline solution[6] nor administration of mineralocorticoid[18] are effective countermeasures.

Our studies after tilt showed significant hemodynamic changes in both the upright and the supine position. Filling pressure and stroke volume were reduced. Saltin et al[2] and Hung et al[19] showed that the stroke volume reduction persists also during supine exercise. The decreased stroke volume is probably a result of reduced preload because cardiac contractility is unchanged.[5,6,20]

The cardiovascular deconditioning induced by bedrest and tilt is generally more apparent in the upright position. Increased compliance of the leg veins with venous pooling could contribute, but estimated calf volumes during lower body negative pressure before and after bedrest in the present study were not different. Alternatively, bedrest and tilt may cause impairment of the reflex mechanisms that normally maintain arterial blood pressure and tissue perfusion in the upright position. Altered baroreflexes after bedrest in monkeys were reported by Billman et al,[20] but similar data in humans are lacking. Arterial vasoconstrictor responses during lower body negative pressure after head-down tilt in our subjects were unchanged, although one may argue that a greater response should have occurred in the presence of hypovolemia after tilt.

Recent studies have identified additional neural mechanisms that may participate in postural cardiovascular responses. Henriksen and Sejrsen[21] described a local reflex that causes vasoconstriction in skeletal muscle and subcutaneous fat in response to venous distension. Thompson and Yates[22] showed that stimulation of venous afferents that respond to stretch increases skeletal muscle tone by a spinal reflex. The effect of bedrest on these reflexes has not been examined.

Other aspects of neurohumoral cardiovascular control mechanisms have been studied, but no clear concepts have emerged. Indirect support for a change in peripheral vascular regulation, mediated by modulation of central mechanisms, is found in a recent report by Norsk et al.[23] Chobanian et al[3] found no bedrest-induced changes in pressor responses to norepinephrine or angiotensin infusions. Schmid et al[24] also found normal vasoconstrictor responses to intraarterial norepinephrine infusions but attenuated effects of tyramine, suggesting normal receptor function but impaired endogenous release.

Clinical implications: Despite the lack of complete understanding of cardiovascular impairment after bedrest, several observations of possible relevance to the cardiac patient can be made. Most important, the central fluid shift and not inactivity is the major factor. Apparently, the reference level or setpoint for central blood volume regulation in man is the upright position. A successful adaptation to the supine position includes decreased end-diastolic volume and filling pressures and decreased total blood volume. These losses and impaired regulatory mechanisms make the patient unable to cope effectively with a further decrease in central blood volume and filling pressures, when the upright position is resumed. Exercise with bedrest is not directed toward the primary problem and cannot be expected to prevent deconditioning. Volume expansion has limited effectiveness[6,21] and could be contraindicated in cardiac patients. Reestablishment of normal upright hydrostatic gradients is an effective countermeasure in bedrest studies in normals[4,25] and may play a similar beneficial role in patients.

The results of this study are not directly transferable to the clinical situation. Patients with heart failure are resistant to orthostatic challenges.[26] Nevertheless, the findings provide a rationale for reemphasis of a 40-year-old therapeutic approach. In 1944, Harrison[27] and Dock[28] identified the cardiovascular problems associated with prolonged bedrest. Levine and Lown subsequently published a classic study of chair rest for patients with acute myocardial infarction and found it to be a safe and desirable form of treatment.[29]

Acknowledgment: We gratefully acknowledge Willie Moore, Jr., for technical support, Kent Dana, MA, and Nancy Campbell, MS, for statistical advice, and Carolyn Donahue for preparation of the manuscript.

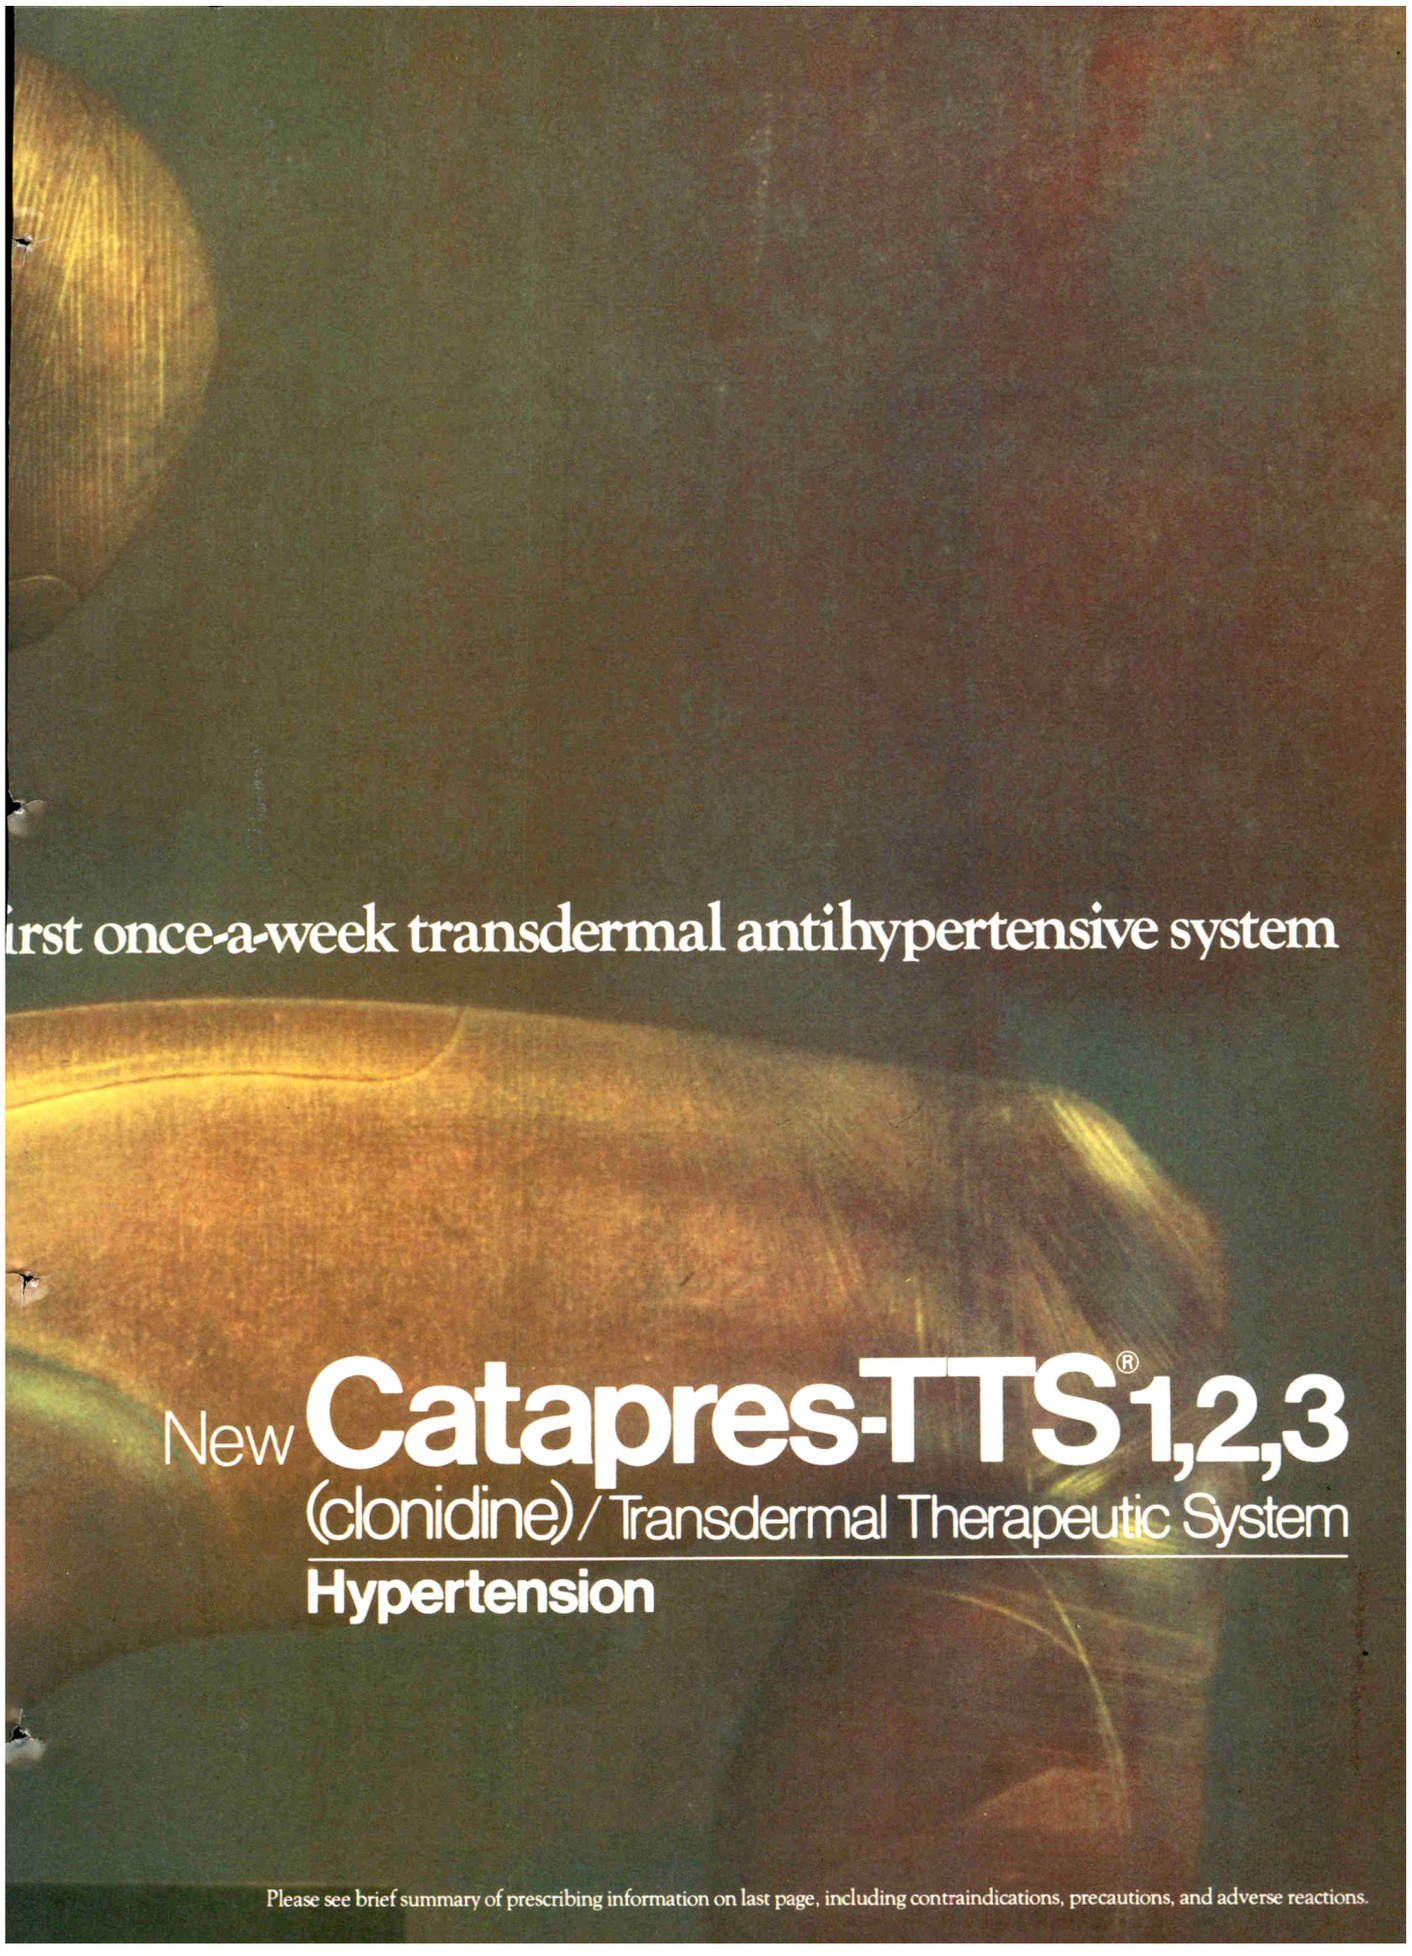
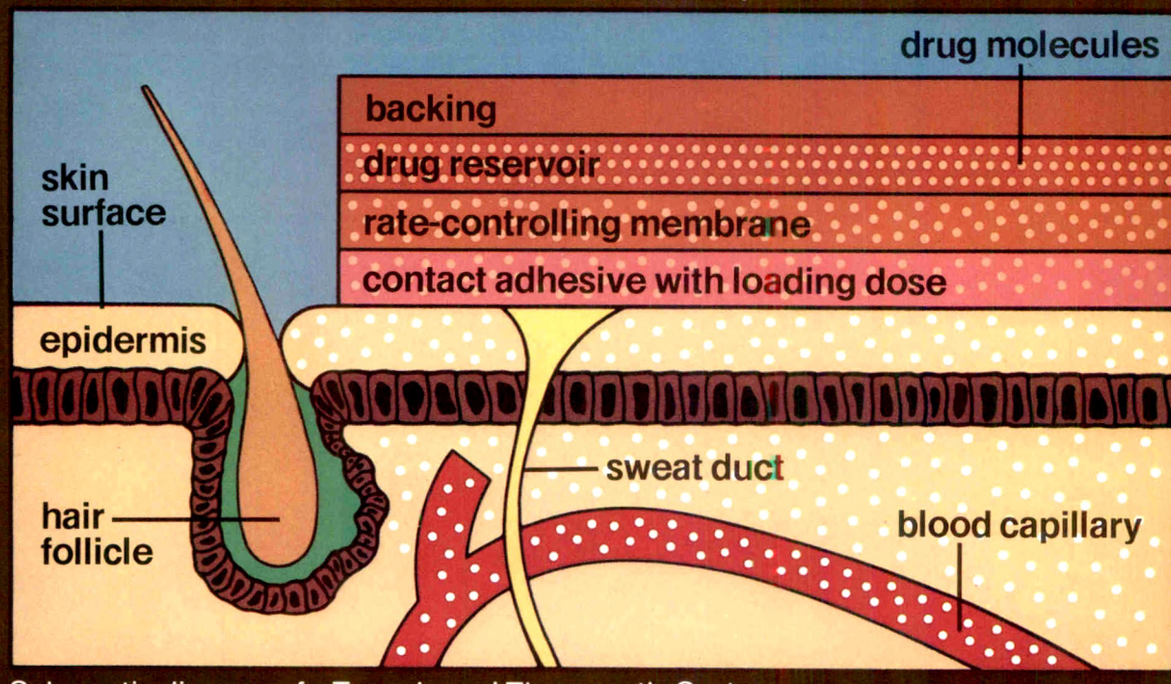
Introducing th



irst once-a-week transdermal antihypertensive system
New Catapres-TTS®1,2,3
(clonidine) / Transdermal Therapeutic System
Hypertension
Please see brief summary of prescribing information on last page, including contraindications, precautions, and adverse reactions.

Continuous 7-day transdermal delivery

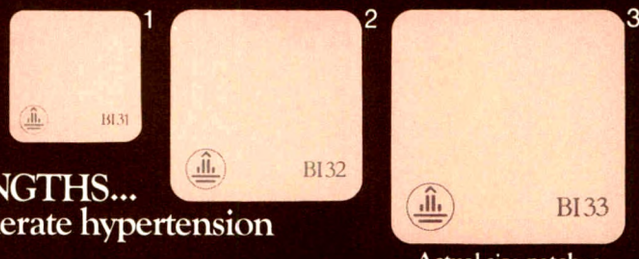


Schematic diagram of a Transdermal Therapeutic System placed in contact with the skin.

New Catapres-TTS®1,2,3

(clonidine) / Transdermal Therapeutic System

Hypertension



Actual size patches

THREE DOSAGE STRENGTHS...
Start with it in mild to moderate hypertension

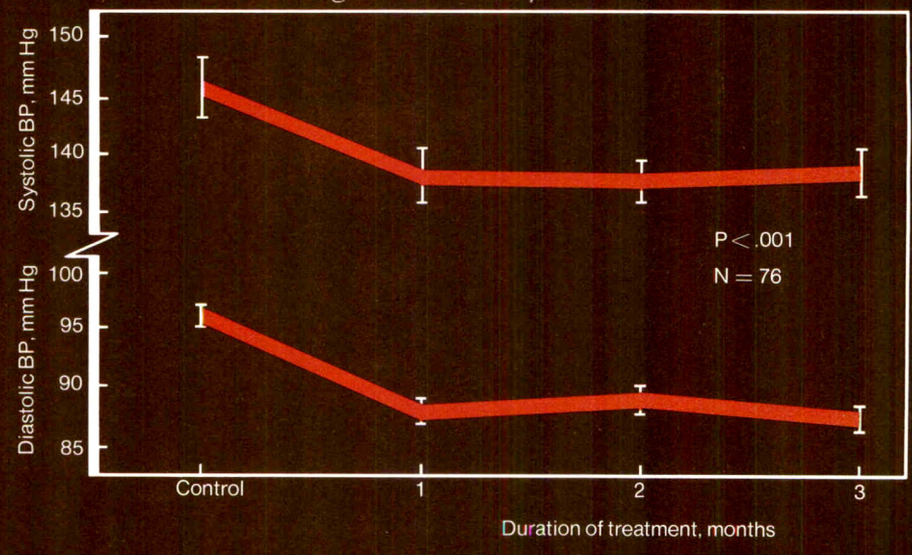
- Convenient once-a-week dosage to aid compliance.
- Effective blood pressure control with or without a diuretic.
- Steady-state blood levels — without the peaks and valleys of oral forms.
- No diuretic-like biochemical effects.
- 24-hour blood pressure control 7 days a week.
- Central control of blood pressure.

Most common side effects are dry mouth and drowsiness, which tend to diminish with time, and mild erythema and pruritus associated with 7-day skin occlusion. After a mean duration of treatment of 24 weeks, contact dermatitis was observed in 16% of patients. This condition resolved upon discontinuation of therapy.

7 days of continuous therapy... a new age of compliance

Documented long-term efficacy

Systolic and diastolic BPs during control (placebo) and after 1, 2, and 3 months of treatment with clonidine administered transdermally. Values are means ± SEMs.[1]



Patch-to-patch applications

Steady-state blood levels — without the peaks and valleys of oral forms

How to use Catapres-TTS®

Three Dosage Strengths for Individualized Therapy
Titrate to proper dosage with Catapres-TTS® alone

1. Start with #1. Replace with #2 and then #3 when necessary to achieve effective blood pressure control.
2. Catapres-TTS® is usually unaffected by showering or other routine daily activities. For some patients, use of an overlay is occasionally required to maintain adequate skin adherence.
3. Most common side effects are dry mouth and drowsiness, which tend to diminish with time, and mild erythema and pruritus associated with 7-day skin occlusion. Contact dermatitis was observed in 16% of patients (100 of 631) treated for a mean duration of 24 weeks. This condition resolved upon discontinuation of therapy.*

Rx

Catapres-TTS 1
x4 Sig: apply once weekly as directed

THREE DOSAGE STRENGTHS...
Start with it in mild to moderate hypertension

The first once-a-week transdermal antihypertensive system

Seven days of effective blood pressure control

- Convenient once-a-week dosage to aid compliance.
- Effective blood pressure control with or without a diuretic.
- Steady-state blood levels—without the peaks and valleys of oral forms

Brief Summary of Prescribing Information

Contraindications: Catapres-TTS® (clonidine) should not be used in patients with known hypersensitivity to clonidine or to any other component of the adhesive layer of the therapeutic system.

Precautions: ***General:*** In patients who have developed localized contact sensitization to Catapres-TTS® (clonidine), substitution of oral clonidine hydrochloride therapy may be associated with development of a generalized skin rash.

In patients who develop an allergic reaction to Catapres-TTS® that extends beyond the local patch site (such as generalized skin rash, urticaria, or angioedema) oral clonidine hydrochloride substitution may elicit a similar reaction.

As with all antihypertensive therapy, Catapres-TTS® should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease, or chronic renal failure.

Withdrawal: Patients should be instructed not to discontinue therapy without consulting their physician. Sudden cessation of clonidine treatment has resulted in subjective symptoms such as nervousness, headache and sweating, accompanied or followed by a rapid rise in blood pressure and elevated catecholamine concentrations in the plasma, but such occurrences have usually been associated with previous administration of high oral doses (exceeding 1.2 mg/day) and/or with continuation of concomitant beta-blocker therapy. Rare instances of hypertensive encephalopathy and death have been reported.

An excessive rise in blood pressure following Catapres-TTS® discontinuance can be reversed by administration of oral clonidine or by intravenous phentolamine. If therapy is to be discontinued in patients receiving beta-blockers and clonidine concurrently, beta-blockers should be discontinued several days before cessation of Catapres-TTS® administration.

Perioperative Use: As with oral clonidine therapy, Catapres-TTS® therapy should not be interrupted during the surgical period. Blood pressure should be carefully monitored during surgery and additional measures to control blood pressure should be available if required. Physicians considering starting Catapres-TTS® therapy during the perioperative period must be aware that therapeutic plasma clonidine levels are not achieved until 2 to 3 days after initial application of Catapres-TTS®.

Information for Patients: Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of a potential sedative effect of clonidine. Patients should be cautioned against interruption of Catapres-TTS® therapy without a physician's advice. Patients should be advised that if the system begins to loosen from the skin after application, the adhesive overlay should be applied directly over the system to ensure good adhesion over its 7-day lifetime. Instructions for using the system are provided. Patients who develop moderate or severe erythema and/or localized vesicle formation at the site of application, or a generalized skin rash, should consult their physician promptly about the possible need to remove the patch.

Drug Interactions: If a patient receiving clonidine is also taking tricyclic antidepressants, the effect of clonidine may be reduced, thus necessitating an increase in dosage. Clonidine may enhance the CNS-depressive effects of alcohol, barbiturates or other sedatives. Amitriptyline in combination with clonidine enhances the manifestation of corneal lesions in rats.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a 132-week oral carcinogenicity study in rats, clonidine hydrochloride produced no carcinogenic effects at doses up to 300 times the maximum recommended human dose of Catapres-TTS® on a mg/kg weight basis.

Pregnancy: Teratogenic Effects. Pregnancy Category C. Reproduction studies performed in rabbits at doses up to 3.1 times the maximum recommended daily human dose of Catapres-TTS® have revealed no evidence of impaired fertility or harm to the fetus due to clonidine hydrochloride. Studies in rats and mice revealed that doses of 500 mcg/kg/day and higher are embryotoxic. One rat study at doses of 15 mcg/kg/day (0.33 times the maximum recommended daily human dose) exhibited embryotoxicity. There are no adequate and well-controlled studies in pregnant women. Although animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: As clonidine is excreted in human milk, caution should be exercised when Catapres-TTS® (clonidine) is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children below the age of 12 have not been

month, multiclinic trial of Catapres-TTS® in 101 hypertensive patients, the most frequen systemic reactions were dry mouth (25 patients) and drowsiness (12 patients).

Transient localized skin reactions, primarily localized pruritus occurred in 51 patients Twenty-six patients experienced localized erythema. This erythema and pruritus were mor common in patients utilizing an adhesive overlay for the entire 7-day treatment period Allergic contact sensitization to Catapres-TTS® was observed in 5 patients.

In additional clinical experience, contact dermatitis was observed in 100 of 631 patient (about 16 in 100) treated for a mean duration of 24 weeks.

The following less frequent adverse experiences were also reported in patients involved i the multiclinic trial with Catapres-TTS®.

Gastrointestinal: Constipation (1 patient); nausea (1); and change in taste (1).

Central Nervous System: Fatigue (6 patients); headache (5); lethargy (3); sedation (3 insomnia (2); dizziness (2); and nervousness (1).

Genitourinary: Impotence/sexual dysfunction (2 patients).

Dermatological: Localized vesiculation (7 patients); hyperpigmentation (5); edema (3 excoriation (3); burning (3); papules (1); throbbing (1); blanching (1); and generalize macular rash (1).

In additional clinical experience involving 3539 patients, less common dermatologic reac tions have occurred, where a causal relationship to Catapres-TTS® was not established maculopapular skin rash (10 cases); urticaria (2 cases); angioedema involving the face (cases), one of which also involved the tongue.

Oro-otolaryngeal: Dry throat (2 patients).
In long experience with oral clonidine hydrochloride, the most common adverse reaction have been dry mouth (about 40%), drowsiness (about 35%) and sedation (about 8%). I addition, the following adverse reactions have been reported less frequently:

Gastrointestinal: Nausea and vomiting, about 5 in 100 patients; anorexia and malaise, eac about 1 in 100; mild transient abnormalities in liver function tests, about 1 in 100; parotitis rarely.

Metabolic: Weight gain, about 1 in 100 patients; gynecomastia, about 1 in 1000; transien elevation of blood glucose or serum creatine phosphokinase, rarely.

Central Nervous System: Nervousness and agitation, about 3 in 100 patients; menta depression, about 1 in 100 and insomnia, about 5 in 1000. Vivid dreams or nightmares, othe behavioral changes, restlessness, anxiety, visual and auditory hallucinations and delirium have been reported.

Cardiovascular: Orthostatic symptoms, about 3 in 100 patients; palpitations and tachycar dia, and bradycardia, each about 5 in 1000. Raynaud's phenomenon, congestive heart fail ure, and electrocardiographic abnormalities (i.e. conduction disturbances and arrhythmias have been reported rarely.

Dermatological: Rash, about 1 in 100 patients; pruritus, about 7 in 1000; hives, angioneu rotic edema and urticaria, about 5 in 1000; alopecia, about 2 in 1000.

Genitourinary: Decreased sexual activity, impotence and loss of libido, about 3 in 10 patients; nocturia, about 1 in 100; difficulty in micturition, about 2 in 1000; urinary retention about 1 in 1000.

Other: Weakness, about 10 in 100 patients; fatigue, about 4 in 100; headache, and discon tinuation syndrome, each about 1 in 100; muscle or joint pain, about 6 in 1000 and cramps o the lower limbs, about 3 in 1000. Dryness, burning of the eyes, dryness of the nasal mucosa pallor, weakly positive Coombs' test, increased sensitivity to alcohol and fever have been reported.

How Supplied: Catapres-TTS®-1 (clonidine), Catapres-TTS®-2 (clonidine) or Catapres TTS®-3 (clonidine) is supplied as 4 pouched systems and 4 adhesive overlays per carton Catapres-TTS®-1 or Catapres-TTS®-2 is supplied in a shipper of 3 cartons.

Consult package insert before prescribing.

Since 1979 most of the cardiac catheterizations at the investigators' institution have been performed as outpatient procedures. All cardiac catheterizations performed over a 66-month period were analyzed. A total of 3,071 outpatient cardiac catheterizations (83% of all cardiac catheterizations) were performed. The percutaneous femoral technique was used in 98% of the procedures. Most patients (79%) had both right and left-sided cardiac catheterization and coronary angiography, which showed significant coronary artery disease (70.4%). Only 13.6% of the study results were normal. Thirty-four patients (1.1%) had major complications, including 4 deaths (0.13%). Seventy patients (2.3%) were admitted for observation only. More than 96% of all patients did not have a major complication and were discharged the same day. Thus, outpatient cardiac catheterization can be performed safely, with a potential reduction in hospital costs and better utilization of medical beds.

(Am J Cardiol 1985;56:639–641)

Cardiac catheterization and coronary angiography have become important and integral components in the investigation of patients with cardiovascular disease. Development of cardiovascular surgical techniques and, more recently, balloon angioplasty, has resulted in a dramatic increase in the number of cardiac catheterizations performed. In a busy hospital this can place a burden both on bed utilization and budgets. We herein report our consecutive series of patients undergoing outpatient cardiac catheterizations by the percutaneous femoral method.

Methods

All patients were initially referred to and evaluated by one of us. A complete history, physical examination and necessary investigations were performed before the catheterization. The procedure was explained and consent was obtained at this time.

Criteria for an outpatient study was up to each cardiologist, but in most cases the only reason for not doing an outpatient cardiac catheterization was that the patient was already in the hospital because of complications of cardiovascular disease such as unstable angina, myocardial infarction or congestive heart failure. Most patients came from the metropolitan area. However, several patients from out of town, if stable and accompanied by a relative, were given the option of outpatient cardiac catheterization and stayed overnight with relatives or in a nearby hotel.

Patients were admitted on the day of the procedure to an outpatient day care facility located within the hospital. After the usual preparation the patient was taken to the cardiac catheterization laboratory. Patients were routinely premedicated with 10 mg of Valium® (diazepam) orally, but there was no routine order for nitroglycerin, heparin or atropine.

Hemostasis after the procedure was achieved by manual pressure and the patient was transferred back to the outpatient area for observation. A sandbag was used to assure hemostasis for 4 hours. After this time, if there were no signs of bleeding, thrombosis or hypotension, the patient was allowed to ambulate for 2 hours further and then discharged. A full-time nurse was in attendance to record vital signs and observe for bleeding or loss of pulse during the patient's stay. Upon discharge the patient was advised not to undertake any activities for the remainder of the day. Full activities were allowed the next day. Written instructions were given to each patient to return immediately to the hospital if signs of bleeding or thrombosis occurred. Patients were followed up by their own physicians and cardiologists within a week of discharge.

Results

We reviewed all the consecutive cases done from January 1979 until June 1984. This was done by reviewing both the Catheterization Laboratory log book and a computerized summary record that detailed the procedures and complications on all patients. A medical record search was done to determine which patients had been admitted to the hospital up to a month after discharge from the catheterization. In addition, each cardiologist kept a record of catheterizations he performed and complications that resulted.

Of 3,694 cardiac catheterizations performed during the 66-month period, 3,071 (83%) were performed as outpatient procedures. Ninety-eight percent of the procedures were performed using the Seldinger technique with Judkins-type preformed catheters; 79% of all patients had both right- and left-sided cardiac catheterization and coronary angiography. Most patients were men (Table I) with coronary artery disease (70.4%). Only 13.6% of all the patients studied had

TABLE I Characteristics of Patients Undergoing Outpatient Cardiac Catheterization

Male	74.0%
Coronary artery disease (>50% stenosis)	70.4%
Valvular heart disease	12.5%
Congenital, cardiomyopathy	3.5%
Normal	13.6%
Total	100%

TABLE II Complications

Mortality	4	0.13%
Arrhythmia	13	0.42%
Myocardial infarction	2	0.07%
Vascular complications	11	0.35%
Neurologic complications	4	0.14%
Other	70	2.30%
No complications—discharged same day	2,967	96.59%
Total	3,071	100%

normal study results. Twenty-seven percent of all patients had 3-vessel disease, 32% had 2-vessel disease, 36% had 1-vessel disease and 5% had significant left main narrowing.

Complications (Table II): Thirty-four patients had significant complications (1.1%). Four patients died. One patient died in the cardiac catheterization laboratory after dissection of the left main coronary artery. This patient had severe 3-vessel disease and previous myocardial infarction. Anaphylactoid shock developed in 1 patient after left ventricular angiography and the patient could not be resuscitated. Two patients died outside of the cardiac catheterization laboratory. One patient suffered out-of-hospital cardiac arrest after he was discharged home. This patient had 2-vessel disease with a previous myocardial infarction and had been stable before, during and after the cardiac catheterization. His predischarge electrocardiogram and examination did not show any signs of ischemia or ventricular irritability. Another patient had a cerebrovascular accident during the procedure and died approximately a week later, secondary to complications related to the stroke.

Thirteen patients had significant arrhythmias requiring either treatment and/or admission to the hospital; 8 of these patients had ventricular tachycardia or ventricular fibrillation, which was successfully treated with lidocaine and or ventricular defibrillation. One patient with significant coronary artery disease had a cardiac arrest approximately 10 hours after discharge from the hospital. He was successfully resuscitated but did suffer long-term neurologic damage. The remaining patients had bradyarrhythmias, which responded to atropine or pacing. None of these patients had further complications.

Only 2 patients had a myocardial infarction within 24 hours after cardiac catheterization. Both patients recovered uneventfully. Eleven patients had vascular complications related to the procedure. Three patients were admitted 2 to 3 weeks after the catheterization for right groin abscesses and were treated with drainage and antibiotics. Six patients required admission after the catheterization for repair of femoral artery aneurysm or endarterectomy. One patient suffered a deep vein thrombophlebitis and 1 patient had an acute embolic episode to the contralateral femoral artery during the cardiac catheterization.

Four patients had a cerebrovascular accident. Two of these patients had only transient symptoms, which resolved completely within 24 hours. One patient who had a history of hypertensive disease for many years had a brain stem infarction during left ventricular angiography. This resulted in permanent residual neurologic damage. Another patient had a cerebrovascular accident during the procedure and died a week later. (This patient is listed as one of the 4 deaths.)

Seventy patients (2.3%) were admitted after the procedure for a variety of reasons, including severity of disease, hypotension, bleeding at the puncture site, vasovagal reactions, allergic reactions and social reasons. More than 96% of patients had no complications and were discharged the same day.

Discussion

The incidence of major complications of cardiac catheterization in previous studies has been well documented. Bourassa and Noble[1] reviewed 5,250 patients studied by the percutaneous femoral approach at the Montreal Heart Institute with a reported mortality rate of 0.23%, a nonfatal myocardial infarction rate of 0.09%, a vascular complication rate of 0.85% and a neurologic complication rate of 0.13%. Potentially serious ventricular arrhythmias were seen in 0.80% of cases. Thus, the total major complication rate in their study was 2.1%. Abrams and Adams[2] reviewed data compiled from a national survey of cardiac catheterization laboratories in 1975. A total of 89,079 patients underwent angiography by both the femoral and brachial methods. They found an average mortality rate of 0.15%, a myocardial infarction rate of 0.23% and cerebral embolism in 0.10% of patients studied by the femoral technique.

More recently, Davis et al,[3] in a collaborative study, prospectively analyzed the complications of coronary arteriography in 7,553 patients. The average mortality rate was 0.20% overall (0.14% femoral and 0.51% brachial procedure), nonfatal myocardial infarction occurred in 0.25% (0.22% femoral and 0.42% brachial), vascular complications in 0.70%, embolic episodes in 0.09% and ventricular fibrillation in 0.63%, yielding a total major complication rate of 1.87% (1.78% for the femoral approach). These studies have been the standard against which all cardiac catheterization laboratories must compare.

In an attempt to improve utilization of health care resources, outpatient cardiac catheterization has been initiated in many laboratories. Early reports from these laboratories suggested that the complication rate could be comparable to that seen with inpatient procedures.[4,5] The most detailed report on outpatient cardiac catheterization by the percutaneous femoral method comes from Mahrer and Eshoo.[6] His group reported on 308 patients and found a mortality rate of 0.30% and a major complication rate of 2.24%. Ninety-one percent of their patients were discharged the same day and 6.8% were admitted for observation. The incidence of major

TABLE III Complication Rates of Coronary Arteriography in Various Studies

1st Author	No. of Pts	Mortality (%)	MI (%)	Vascular (%)	CNS (%)	Arrhythmias (%)	Total (%)
Bourassa[1]	5,250	0.23	0.09	0.85	0.13	0.80	2.1
Abrams[2]	89,079	0.15	0.23	. . .	0.10	. . .	. . .
Davis[3]	7,553	0.20	0.25	0.70	0.09	0.63	1.87
Mahrer[6]	308	0.30	0.97	0.65	0.32	. . .	2.24
Present study	3,071	0.13	0.07	0.35	0.14	0.42	1.1

CNS = central nervous system; MI = myocardial infarction.

complications in our series (1.1%) compares favorably with both the inpatient and outpatient series previously reported (Table III). Our mortality rate of 0.13% is at least as good as or exceeds the reported rates. Ninety-six percent of our patients were discharged the same day of the procedure.

The 2 patients who had out-of-hospital cardiac arrest after discharge deserve further comment. One patient died and the other patient had permanent residual neurologic deficit as a consequence. Both patients had significant multivessel coronary artery disease, but were in stable condition before and after the procedure. Patients with serious coronary artery disease are at risk for major cardiac events such as myocardial infarction, arrhythmias or death as a result of the natural history of their disease. The incidences of such pseudocomplications occurring just before or within 24 hours after a planned but unperformed cardiac catheterization is reported to be 2.3%, including a death rate of 1.2%.[7]

Although there was a temporal relation to the cardiac catheterization in our 2 patients, it is difficult to determine a causal relationship. In addition, it is speculative as to whether or not the outcome of resuscitation might have been different if they had been inpatients. The incidence of this complication (0.065%) is well within the probability of natural occurrence for patients with cardiac disease.

In conclusion, the present study indicates that outpatient cardiac catheterization is safe and feasible and may reduce the cost of evaluation of cardiac disease.

Relation of Hemoglobin A_1 and Blood Glucose to Cardiac Function in Diabetes Mellitus

RICHARD S. GOLDWEIT, MD, JEFFREY S. BORER, MD, LOIS G. JOVANOVIC, MD, ANDREW J. DREXLER, MD, CLARE A. HOCHREITER, MD, RICHARD B. DEVEREUX, MD, and CHARLES M. PETERSON, MD

To examine the relation of short- and long-term changes in glucose metabolism to cardiac function, radionuclide cineangiography and echocardiography were performed in 10 young insulin-dependent diabetic patients without clinical evidence of heart disease. Cardiac assessments were performed before and after both acute variations in blood glucose, and induction of chronic "tight glucose control" involving normalization of hemoglobin A_1 concentrations. In diabetic patients, left ventricular (LV) ejection fraction (EF) at normal blood glucose concentration was indistinguishable from values in 11 normal subjects. However, during hyperglycemia (about 300 mg/dl), the average EF at rest was 61%, significantly higher than that during normoglycemia (56%, $p < 0.001$). No significant change in LV diastolic dimension was noted in association with shifts between high and normal blood glucose concentrations. Normalization of hemoglobin A_1 was achieved within 6 to 25 weeks. This alteration had no significant effect on LVEF, mitral valve E-F slope, or the response of systolic function to blood glucose levels. In addition, no correlation was found between LVEF and hemoglobin A_1 concentrations in 4 of 5 evaluation periods. Thus, in young insulin-dependent diabetic patients without overt heart disease, variation in blood glucose concentration is associated with small but significant variation in EF at rest; normalization of hemoglobin A_1 has no significant effect on LVEF or the response of systolic function to blood glucose levels.

(Am J Cardiol 1985;56:642–646)

The association between diabetes mellitus and clinically important cardiac disease has long been recognized, but the effects of acute and chronic control of glucose metabolism on cardiac function in the diabetic patient are not well defined. Although coronary artery disease is the most common cause of clinical cardiac debility in the diabetic patient,[1] clinical,[2–6] epidemiologic,[7] experimental[8,9] and autopsy data[2,10] suggest that primary myocardial dysfunction also may result from diabetes. However, both the existence of such a condition[11,12] and its relation to clinical control of glucose metabolism remain unclear. Many proteins are glycosylated in the poorly controlled diabetic patient,[13–15] and extrapolation from this observation[16–18] suggests that elevated blood concentrations of hemoglobin A_1, a glycoprotein indicator of the chronic (approximately 6 weeks) average blood glucose level,[13] may occur concomitantly with glycosylation reactions involving myocardial proteins. An excess of myocardial glycoproteins has been noted at autopsy in diabetic patients without other apparent heart disease and in animals with experimentally induced diabetes mellitus, and has been associated with diminution of both left ventricular (LV) compliance and systolic functional reserve.[2,8] Therefore, to assess prospectively the cardiac functional effects of both acute variations in blood glucose and of chronic "tight blood glucose control," defined as involving normalization of hemoglobin A_1, we performed radionuclide cineangiography and echocardiography in 10 young diabetic patients without clinically apparent cardiomyopathy.

Methods

Ten patients (7 men and 3 women), aged 21 to 30 years, with insulin-dependent diabetes mellitus were studied. No patient had evidence of coronary artery or other cardiac disease, and none had a systemic disorder other than diabetes that might affect the heart. The mean duration of known diabetes was 7 years (range 3 weeks to 18 years). All patients were within 20% of ideal body weight. Two patients had proliferative diabetic retinopathy. All patients were receiving insulin therapy before and during the study. Before the study, all patients had normal blood urea nitrogen and creatinine levels.

The study design is depicted in Figure 1. Patients were admitted to the Clinical Research Center; morning insulin was withheld until the blood glucose level was elevated to approximately 300 mg/dl. Baseline noninvasive assessment of cardiac function was then undertaken (C_1). After initial determinations, closed-loop insulin therapy (see later) was

carried out during a 4-hour period to bring blood glucose levels into normal range, approximately 80 mg/dl. Examination of LV function was then repeated (C_2). Closed-loop insulin therapy was used to maintain normoglycemia until the next morning, when LV function again was assessed (C_3). The patients were then discharged from the hospital, and treated with insulin therapy using home glucose monitoring (see later). This regimen was continued for at least 6 weeks, until chronic normoglycemia had developed as indicated not only by patient-monitored glucose determinations but also by normalization of hemoglobin A_1. Patients were readmitted for noninvasive cardiac assessment while normoglycemic (C_4). Insulin was withheld for 4 hours, permitting blood glucose levels to rise with administration of a glucose load, again to approximately 300 mg/dl, at which point the final cardiac assessment was undertaken (C_5). The direction of acute alteration in blood glucose was reversed (high to normal vs normal to high) at C_1, C_2 vs C_4, C_5 to eliminate potential methodologic bias or diurnal influences in assessing the effects of such alterations. All cardiac assessments were performed approximately 3 hours after meals.

Two methods of closed-loop insulin therapy were used to achieve rapid alterations in blood glucose concentration. During the first hospitalization between C_1 and C_2, 7 patients were treated using an artificial endocrine pancreas (Biostator®, Life Science Instruments). To eliminate potential saline load effects that may accompany use of the Biostator, in-hospital manipulation of blood glucose was achieved at all other times by a "manual closed-loop system," consisting of fingerstick blood glucose determinations and administration of either intravenous insulin or oral glucose loads.

Outpatient insulin therapy consisted of a previously described split-dose sliding scale insulin regimen and home glucose monitoring system[19] to effect normalization of hemoglobin A_1.

At each cardiac assessment (C_1 to C_5), Biostator plasma glucose readings or reflectance colorimeter blood glucose determinations[19] were performed and were confirmed by assessment of plasma glucose by standard techniques. Plasma glucose measurements are approximately 15% higher than blood glucose determinations (to which all plasma glucose measurements were converted).

Chronic "blood glucose control" was assessed by determination of hemoglobin A_1 levels at weekly intervals. Blood samples were saline-incubated according to the method of Goldstein et al[20] to minimize effects of acute blood glucose changes on hemoglobin A_1 measurements, and were chromatographed the following day. Total glycosylated hemoglobin was determined in triplicate by ion exchange chromatography using a prepacked microcolumn (Quik-Column,® Helena Laboratories). Follow-up cardiac evaluation was performed when the final hemoglobin A_1 concentration was within normal range (5.9 to 8.9%). Initial and final (post-treatment) hemoglobin A_1 concentrations used in analysis were each the average of 3 separate determinations made within a period of 2 weeks.

Noninvasive cardiac evaluation at each assessment point (C_1 to C_5) included M-mode echocardiography at rest and radionuclide cineangiography performed at rest and exercise as indicated in Figure 1. Echocardiographic determinations were made using standard techniques and measurement criteria.[21] LV diastolic dimension (DD) and mitral valve E to F slope (MVEFS) were determined as the mean of measurements from 3 consecutive cardiac cycles. Gated equilibrium radionuclide cineangiography, using technetium-99m-labeled red cells, was carried out with the patient at rest in the modified left anterior oblique[22] and right anterior oblique positions, and during maximal symptom-limited supine bicycle exercise in the modified left anterior oblique position. Data were collected by methods analogous to those previously described.[22–24] After images and time-activity curves were obtained with the patient at rest, bicycle ergometry was begun at a load of 25 W, with increments of 25 W at 2-minute intervals. Exercise was continued at assessment C_1 until fatigue or dyspnea prevented further exercise; at subsequent exercise studies, exercise was continued until the patient had reached an external workload and heart rate indistinguishable from that at C_1. This endpoint generally was also associated with limiting dyspnea or fatigue. Imaging always included the final 2 minutes of exercise.

Radionuclide cineangiographic data obtained in the diabetic patients were compared with data obtained in 11 age-matched normal volunteers (10 men and 1 women, aged 19 to 30 years) without clinical, electrocardiographic or echocardiographic evidence of cardiac abnormalities. Previous studies in large groups of normal subjects in our laboratories, including subjects aged 19 to 30 years, have indicated that LV ejection fraction (EF) varies between 45 to 75% when such subjects are at rest, and that during exercise to heart rates of 110 beats/min or higher (the range achieved in our diabetic patients), EF invariably exceeds 54%, and increases at least 5% during exercise.[25,26]

Data are expressed as mean ± standard error of the mean. Statistical assessments were performed with Student t tests for paired and unpaired data (as appropriate) and with linear regression analysis.[27] "Multiple look" bias theoretically may affect conclusions based on this approach because one can generally expect that 1 in 20 p values will be <0.05 when no difference exists. However, the highly statistically significant differences (<0.001) noted among results obtained at different assessment points in the protocol quantitatively indicate that these differences can be expected to be real.

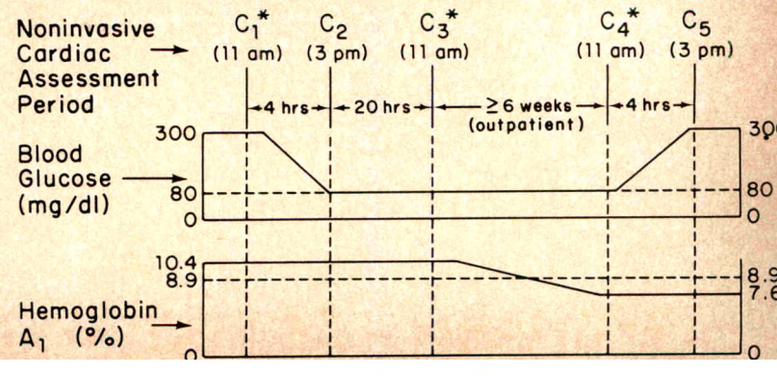

FIGURE 1. Study design. Diabetic patients progressed sequentially (**left** to **right**) through the noninvasive cardiac assessments. The state of glucose metabolism control was therapeutically altered in accordance with the upper and lower diagrams, which represent blood glucose and hemoglobin A_1 levels, respectively. Normal hemoglobin A_1 is less than 8.9%. C_1 to C_5 = cardiac assessment periods. *When radionuclide cineangiography was performed both at rest and during exercise.

Results

The results of manipulation of blood glucose are shown in Figure 2. Hemoglobin A_1 concentrations were supernormal at baseline in 9 of 10 patients. Average hemoglobin A_1 decreased from 10.4 ± 0.5% to 7.6 ± 0.2% ($p < 0.001$) after a period of 6 to 25 weeks of outpatient insulin therapy. Moderate hyperglycemia was achieved at cardiac assessments C_1 and C_5 and the average blood glucose level was less than 100 mg/dl at all other assessments.

At each evaluation (C_1 to C_5), none of the 10 patients demonstrated regional LV dysfunction. Moreover, when blood glucose levels were within normal range, mean EF values for patients were statistically indistinguishable from those of normal subjects (Fig. 3). All patients had a normal increase in EF with exercise at each of the 3 assessments in which exercise was performed. No significant changes in heart rate and blood pressure were noted at different assessment points (C_1 to C_3).

However, a small but significant variation in EF at rest was noted in association with variation in blood glucose (Fig. 4). During hyperglycemia, average EF at rest was significantly higher than during normoglycemia. This relation was present when C_1 values were compared with those obtained after either 4 or 24 hours of therapy. EF during exercise did not vary significantly with blood glucose changes (exercise EF C_1 = 74 ± 3, EF C_3 = 72 ± 3%, difference not significant [NS]). After normalization of hemoglobin A_1, the variation of EF at rest with blood glucose again was noted (Fig. 4), although the sequence of glucose alterations was reversed as compared with C_1, C_2.

Achievement of chronic blood glucose control, as indicated by the normalization of hemoglobin A_1, had no significant effect on EF at rest, either during normoglycemia or during hyperglycemia (Fig. 4), or during exercise (exercise EF C_4 = 72 ± 4%, NS vs C_3). Moreover, regardless of blood glucose concentration, no significant correlation existed between hemoglobin A_1 and EF at rest except for rest EF C_3 where the correlation coefficient ($r = -0.70$) reached minimal statistical significance ($p < 0.05$). No significant correlation existed between hemoglobin A_1 and EF during exercise at any evaluation period.

Echocardiographic assessment revealed no significant difference between average LVDD when blood glucose was normal (LVDD C_2 = 4.7 ± 0.2 cm) and when blood glucose was elevated (LVDD C_1 = 4.8 ± 0.1 cm [NS vs C_2]). Moreover, during all assessments of the diabetic patients, LVDD was within the range measured in normal subjects. In addition, no significant change in LVDD resulted after normalization of hemoglobin A_1 (LVDD C_4 = 4.8 ± 0.2 [NS vs C_2], C_5 = 4.8 ± 0.2 cm [NS vs C_1]). Thus, the decrements in LVEF manifested on normalization of blood glucose occurred without echocardiographic evidence of significant LV diastolic volume change.

Echocardiographic assessment of MVEFS showed that although 2 patients manifested subnormal MVEFS (less than 50 mm/s) before outpatient therapy, values for all patients were virtually unchanged after normalization of hemoglobin A_1 (MVEFS C_1 = 64.9 ± 6.0, C_5 = 68 ± 6.0 mm/s, NS) or acute shifts in blood glucose

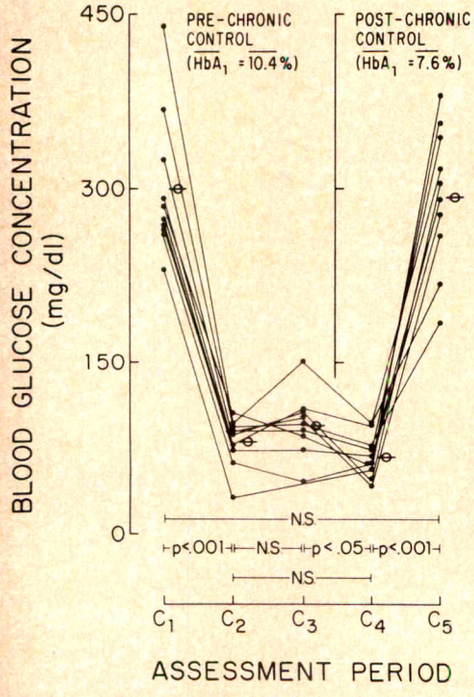

FIGURE 2. Blood glucose concentration at each cardiac assessment period both before and after normalization of hemoglobin A_1 (CHRONIC CONTROL). One patient did not undergo cardiac assessment at C_3. Θ = average values; C_1 to C_5 = cardiac assessment periods; HbA_1 = average hemoglobin A_1; N.S. = not significant.

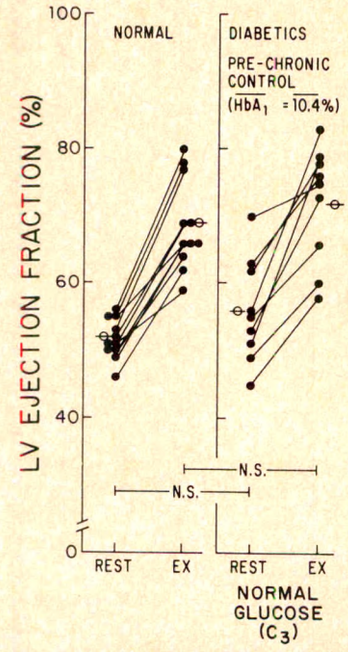

FIGURE 3. Effect of maximal exercise (EX) on left ventricular (LV) ejection fraction in normal subjects, and in diabetic patients during assessment period C_3, when the blood glucose level was normal (mean blood glucose 94 mg/dl). Abbreviations as in Figure 2.

(MVEFS C_2 = 73 ± 6.0 [NS vs C_1], C_4 = 65 ± 7.0 mm/s [NS vs C_5]). Thus, no change in this index of LV compliance[28] was detected during the interventions used.

Discussion

Patients with diabetes mellitus frequently manifest clinical evidence of cardiac disease, primarily in association with abnormalities of the coronary arteries.[1] Evidence for a "diabetic cardiomyopathy" in the absence of coronary disease has only recently accumulated,[2–10] and its existence, pathogenesis and clinical importance remain controversial.[11,12] Further, the capacity for modification of LV function in the diabetic patient by shifts in blood glucose and insulin concentrations (which substantially modify cardiac metabolism[18] and may cause glycosylation of myocardial proteins[16–18] with resultant alteration in cardiac structure and function[2,8]) is poorly understood.

Our findings indicate that moderate hyperglycemia in the young diabetic patient is associated with a small increase in LVEF at rest compared with results obtained in the normoglycemic state. This relation between EF and blood glucose is not mitigated by chronic tight glucose control involving normalization of hemoglobin A_1, and it is not clear which of many mechanisms may explain such an effect. Although echocardiographic measurements suggested that no significant alteration in end-diastolic volume occurred in association with acute changes in blood glucose, we cannot preclude the possibility that small volume shifts may have occurred, undetected by our methods, changing EF in accordance with the Frank-Starling relation. Also, high concentrations of blood glucose, like mannitol, exert osmotic effects that can alter cardiac function by dilating resistance vessels, increasing coronary blood flow,[29] causing autonomically mediated responses[30] and enhancing inotropic state.[31] Moreover, in diabetic patients, changes in the relative amounts of glucose and insulin exert complex effects on glucose utilization, adenosine triphosphate levels, and β oxidation of free fatty acids, which may also result in alterations in contractile function.[18]

Our results suggest that acute changes in glucose metabolism can cause small but significant modification of cardiac function in the diabetic patient. The association of blood glucose and EF may be of clinical importance. Evaluations of LV function in patients with diabetes mellitus should be performed with the knowledge that the blood glucose at the time of testing may affect results. Whether acute changes in blood glucose and resultant small changes in cardiac function are of significance for the diabetic patient with heart disease would appear to be dependent on the mechanism by which glucose acts on the myocardium, and requires further direct study for elucidation.

Our results indicate that normalization of hemoglobin A_1 in young diabetic patients without cardiac symptoms has no significant effect on systolic or diastolic LV performance. Other investigators show that accumulation of interstitial glycoprotein occurs in the myocardium in chronically uncontrolled diabetes and is associated with altered ventricular compliance.[2,8] Our findings are consistent with these earlier results in that 2 patients manifested clearly subnormal echocardiographic E-F slope, and the group as a whole evidenced an average value near the lower end of the normal range. Echocardiography provides only an estimate of diastolic function[28] and more sensitive indexes may be required to detect alterations in diastolic function caused by altered glucose levels.

Although our data failed to show a significant relation between chronic glucose control and cardiac function, conclusions based on these data must be guarded. Previous investigations suggest that diabetic women, and patients with diabetic retinopathy or nephropathy,[4,7] appear most likely to manifest cardiomyopathic findings. Only 3 women and 2 patients with proliferative retinopathy were included in our study group, and at baseline none of our patients manifested subnormal systolic function and only 2 evidenced diastolic dysfunction. Thus, the paucity of detectable preexisting systolic and diastolic abnormalities may have precluded observation of a significant effect of hemoglobin A_1 normalization. Also, although myocardial protein degradation is increased in diabetic rats,[32] the rate of acquisition or turnover of glycosylated myocardial proteins is not known. Therefore, longer periods of improved diabetic control, more sensitive techniques, or assessment of a different diabetic patient population, might possibly have provided different results. Further study is needed to clarify these points.

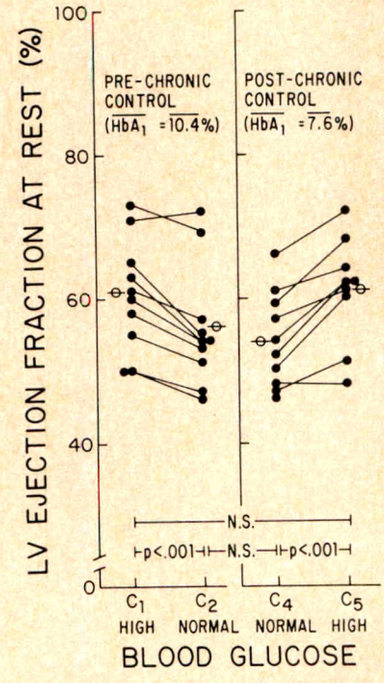

FIGURE 4. Effect of blood glucose concentration on systolic left ventricular (LV) performance at rest in diabetic patients as determined by ejection fraction. Results of cardiac evaluation at C_5 were not obtained in 1 patient because of technical difficulties. HIGH = approximately 300 mg/dl; NORMAL = approximately 80 mg/dl; other abbreviations as in Figure 2.

Electrophysiologic Evaluation of the Cardiac Conduction System and Its Autonomic Regulation in Familial Amyloid Polyneuropathy

BO LENNART BERGFELDT, MD, PhD, BERT-OVE OLOFSSON, MD, PhD, and KNUT OLOF EDHAG, MD, PhD

A high incidence of cardiac conduction disturbances is a salient feature in familial amyloid polyneuropathy (FAP) and amyloid infiltration of the conduction system has been found. In patients with FAP autonomic nervous dysfunction involving gastrointestinal, urogenital and cardiovascular systems has been described. However, the present study is the first to evaluate the results of autonomic tests and pharmacologic intervention in the autonomic nervous regulation of the cardiac conduction system during an invasive electrophysiologic study. Seven patients with FAP and severe disturbances of the conduction system, evaluated concerning indications for pacemaker treatment, were studied; in 3 of them the parasympathetic regulation was found to be abolished. In 1 patient the observations indicated either vagal overactivity or denervation oversensitivity of the receptors. The function of the β adrenoceptors was intact in all patients, but a disturbance of sympathetic innervation could not be excluded. Dysfunction of autonomic nervous regulation of the cardiac conduction system was thus found in 4 of 7 patients. However, most conduction abnormalities were irreversible, indicating amyloid infiltration of the conduction system as the predominant pathophysiologic mechanism, in accordance with the findings of pathoanatomic studies.

(Am J Cardiol 1985;56:647–652)

Familial amyloid polyneuropathy (FAP) is characterized by generalized amyloidosis and sensorimotor and often also autonomic neuropathy.[1] Amyloid deposits have been demonstrated in the myocardium as well as in all parts of the conduction system in patients with FAP,[2,3] and atrioventricular conduction disturbances[4–6] and sinus node dysfunction[7] are important clinical manifestations. At least 10% of Swedish patients with FAP require permanent pacemaker therapy.[8] In a previous report the presence of autonomic neuropathy of the heart was suggested, but the function of the sinus node was not evaluated, leaving the question of the site of the dysfunction unanswered.[9] An electrophysiologic study on Japanese patients has been reported, which was not designed, however, to test the autonomic regulation.[10]

The purpose of the present study was to investigate the cardiac conduction system and its autonomic nervous regulation in patients with FAP.

From the Cardiac Divisions, Departments of Internal Medicine, Huddinge University Hospital, Huddinge, and Umeå University Hospital, Umeå, Sweden. This study was supported by a grant from the Swedish National Association Against Heart and Chest Diseases and a research fellowship to Dr. Bergfeldt from the County Council of Stockholm. Manuscript received December 20, 1984; revised manuscript received April 25, 1985, accepted April 29, 1985.

Methods

Seven patients, representing approximately 10% of the Swedish patients with FAP who are alive, were examined. All of them had a typical clinical picture and rectal or skin biopsy verified amyloidosis. Heart biopsies were not performed. Indirect evidence of cardiac amyloidosis was obtained from standard electrocardiograms in all patients, echocardiograms in all but patient 6 and heart scintigrams in patients 1 and 3 (Table I). As no other cause of heart disease was found, the New York Heart Association criteria of cardiac amyloidosis were fulfilled.[11]

The main electrocardiographic diagnosis was atrioventricular block of varying degree in patients 1, 2, 3, 4 and 5 and sinus node dysfunction in patients 6 and 7, in the latter case combined with atrial flutter. They had all experienced symptoms that could be attributed to bradyarrhythmias, except patients 4 and 7, and the electrophysiologic study was part of the evaluation for pacemaker therapy.

Functional classification (Table I): A 4-grade classification of the severity of the polyneuropathy has been presented previously.[12] This is essentially equivalent to the recommendations of the New York Heart Association for classification of cardiac functional status,[13] which were also applied in this study, except in patient 1, with the most severe degree of polyneuropathy.

Analysis of electrocardiographic recordings: Definitions and terms related to cardiac rhythm follow the recommendations of Hecht et al[14] and Robles de Medina et al.[15] Long-term electrocardiographic recordings of a duration of at least 24 hours were analyzed both automatically and manually.

TABLE I Clinical Data and Functional Classification of Seven Patients with Familial Amyloid Polyneuropathy and Cardiac Conduction Disturbances Investigated Electrophysiologically

Pt	Age (yr) & Sex	Duration of Polyneuropathy (yr)	Degree of Polyneuropathy	Cardiac Function (NYHA class)	Cardiomegaly	Echo	Cardiac Scintigram

3	60M	6	++	III	+	Typical	Typical
4	66M	7	++	I	0	Typical	...
5	42F	7	++	II	0	Typical	...
6	49F	16	+++	II	0	Normal	...
7	65F	7	++	II	+	Typical	...

Echo = echocardiogram; NYHA = New York Heart Association; + = present; 0 = absent; ... = not performed.

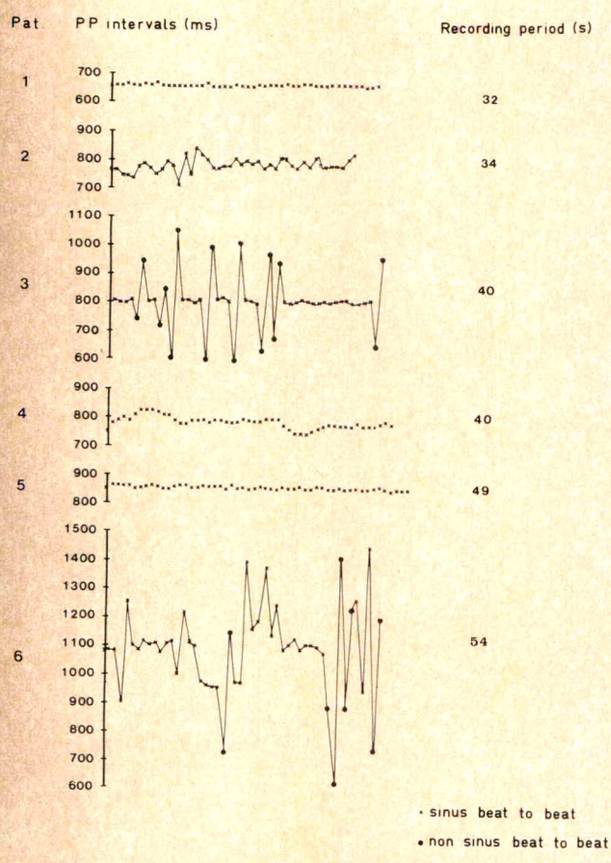

FIGURE 1. Spontaneous variations in atrial activity recorded during the electrophysiologic study—consecutive PP intervals. Patient 1—minimal variations in sinus node activity, implying lack of vagal influence, consistent with the absence of response to carotid sinus pressure and atropine injection. Patient 2—beat-to-beat variations within reference limits,[22] but of an unsystematic kind, which may be due to the sinus node dysfunction. Patient 3—pronounced beat-to-beat variations resulting in nodal extrasystoles with compensatory pauses. Sinus node activity with minimal variations consistent with the lack of response to carotid sinus pressure and atropine injection. Patient 4—variations in sinus node activity in a continuous undulating mode within reference limits, consistent with normal sinus node function and normal responses to carotid sinus pressure and atropine injection. Patient 5—minimal variations in sinus node activity, implying impaired vagal function, consistent with the absence of response to carotid sinus pressure and the minimal response to atropine injection. Patient 6—increased sudden variations in sinus node activity occurring in a haphazard way, possibly reflecting the sinus node dysfunction. Even greater variations due to ectopic supraventricular beats are seen. Patient 7—had constant atrial flutter.

Other investigative procedures: Echocardiographic examination was performed according to the routine procedure and amyloid infiltration was diagnosed in the presence of hyperrefractile echoes and left ventricular hypertrophy.[16–18]

Heart scintigrams were recorded and interpreted by procedures described previously. A pattern that is typical, although not completely specific, for FAP has been described[19] and was found in patients 1 and 3.

Electrophysiologic study: The patients were in the nonsedated, postabsorptive state during the investigation. Pharmacologic treatment known to affect the cardiac conduction system was withheld for more than 5 half-lives before the investigation, at which time no measurable amounts were found in blood samples. All patients had given their informed consent and the investigation protocol was approved by the Medical Ethics Committees of the hospitals.

Two No. 6Fr electrode catheters with a 1-cm interelectrode distance were introduced percutaneously under local anesthesia through a femoral vein. A quadripolar catheter was positioned high in the right atrium against the lateral wall for simulation and recording. A tripolar electrode catheter was positioned across the tricuspid valve for recording of low atrial activity and the His bundle potential. The intracardiac electrogram and surface leads I, II, V_1 and V_6 were continuously recorded on a multichannel Mingograph (Siemens-Elema) with frequency limits of 50 and 700 Hz at a paper speed of 100 mm/s. Pacing was performed with a stimulus duration of 2 ms at a voltage of 2 to 3 times the stimulation threshold, using a stimulator for programmed pacing (Devices Ltd).

Investigation protocol: Recordings of spontaneous heart rhythm and conduction intervals were first obtained in the basal state and later analyzed for beat-to-beat variations of sinus node activity (Fig. 1).

Carotid sinus pressure was then applied for 2 periods of 10 seconds on each side. PP and AH intervals were measured as the average of at least 5 and 3 intervals, respectively, immediately before and during carotid sinus pressure.

The sinus node recovery time was determined by atrial pacing for periods of 10 seconds (3 times) and 30 seconds (2 times) at atrial rates of 90 and 130 beats/min. The longest recovery time was chosen and corrected for heart rate by subtracting the mean of 5 PP intervals immediately before the pacing period.

The paced atrial rate at Wenckebach block was determined by incremental pacing, with increments of 10 impulses per minute (ipm)/10 seconds, starting at a rate slightly above the resting rate. The refractory period of the atrioventricular node was determined by delivering 1 atrial extrastimulus at decreasing intervals coupled to a 5-second period of regular pacing at 100 ipm or the highest possible rate below 100 ipm.

It was defined as the longest nonconducted extrastimulus interval.

Isoproterenol, 0.1 μg/kg body weight, was then given intravenously (i.v.) over 30 seconds. The maximal heart rate[20] and the change in heart rate was determined.

Atropine, 0.02 mg/kg body weight, was given i.v. over 30 seconds when the heart rate had returned to the level before isoproterenol or when 20 minutes had elapsed. PP and AH intervals, the atrial rate at Wenckebach block and the refractory period of the atrioventricular node were determined before and after atropine administration.

Propranolol, 0.1 mg/kg body weight, was given i.v. over 30 seconds as soon as possible and usually 10 minutes after the atropine injection. All aforementioned conduction intervals and functional tests were then repeated during this pharmacologic inhibition of autonomic tone.

Statistical methods: A Student *t* test for paired observations was used to compare results obtained under different conditions, with a significance level of $p < 0.05$.

Results

The conduction intervals, uncorrected and corrected sinus node recovery times, atrioventricular nodal refractory periods and atrial rates at Wenckebach block recorded with the patients in the basal state and after inhibition of autonomic tone by atropine and propranolol are presented in Table II. Patient 7 had atrial flutter, which could not be terminated.

In summary, most patients had widespread involvement of the conduction system, and 5 received pacemaker treatment (Table III).

Interference with parasympathetic regulation of the heart (Table IV, Fig. 1): The comparison of data obtained during different conditions did not show any general significant difference, but there were great interindividual differences.

Parasympathetic stimulation by carotid sinus pressure did not cause any changes in PP or AH intervals in patients 1, 3 and 5, and *parasympathicolysis* with atropine had no effect or only a minimal effect on sinus nodal and atrioventricular nodal function. Figure 1 shows minimal variations in sinus node activity in the same patients. These results were probably a result of severely impaired or abolished vagal regulation of the cardiac conduction system. In the other patients carotid sinus pressure or atropine, or both, induced changes, indicating residual vagal influence on impulse formation

Patient 2 had sinus rhythm in the basal state, with first- and second-degree atrioventricular block in the atrioventricular node. Both atropine and isoproterenol abolished second-degree atrioventricular block and normalized the atrioventricular nodal refractory period and the Wenckebach rate.

Interference with sympathetic regulation of the heart: The heart rate response to isoproterenol was normal in all patients, with a rate increase to more than 90 beats/min.[20] The average increase in heart rate was 76% (range 30 to 155%, $p < 0.01$). A comparison between the measurements in the basal state and after administration of isoproterenol and atropine/propranolol showed that the β receptors of the conduction system in all patients reacted to β stimulation as well as to β blockade.

Discussion

It has been proposed that FAP may involve the autonomic nervous system,[7] and de Freitas et al[9] suggested that defective autonomic regulation of the heart may occur, but in their study the function of the cardiac conduction system was not evaluated.[9]

In a recently reported study,[10] 8 Japanese patients with FAP were investigated electrophysiologically. Two had prolonged sinus node recovery time. Wenckebach block occurred at low atrial rates, between 77 and 120 ipm in all 8, of whom 4 also had prolonged refractory period of the atrioventricular node; 3 had an HV interval exceeding 60 ms. Isoproterenol (continuous i.v. infusion, 0.5 μg/min) improved impulse formation and conduction as expected. However, atropine (1 mg i.v.), unexpectedly impaired sinus nodal and atrioventricular nodal function in most of their patients, which was not observed in our patients. Neither parasympathetic stimulation nor β-receptor blockade was attempted and no conclusions could be made concerning the cardiac innervation.[10]

The present study is the first to combine evaluation of the function of the cardiac conduction system and its autonomic regulation in FAP patients, and the first to unequivocally show autonomic neuropathy of the heart. The advantages of performing tests on autonomic heart regulation during an electrophysiologic study rather than during a conventional standard

Functional evaluation of the whole conduction system was possible and the ability of the heart to respond to autonomic stimuli could thus be assessed. (2) The origin of spontaneous atrial activity could be accurately defined (patient 3, Fig. 1). (3) Three measures of atrioventricular nodal function were obtained: conduction time (AH interval), atrioventricular nodal refractory period, and atrial rate at Wenckebach block. All of them are influenced by autonomic nervous activity, like the PP interval, which, often is the only variable recorded in connection with autonomic tests.

The tests we used require comment: (1) Carotid sinus pressure is difficult to standardize, and dysfunction at any site along the reflex arc may cause an abnormal or absent response. (2) Atropine acts on the neuroeffector junction, and improvement of sinus nodal and atrioventricular nodal function after atropine administration must therefore be interpreted as an antagonism of preexisting vagal activity. (3) The normal spontaneous beat-to-beat variations depend on complex brain stem reflexes, with respiration as the main stimulus, and require an intact vagal system.[22] The results of these 3 different tests on parasympathetic function were concordant in all patients investigated (Table IV, Fig. 1). The results recorded in patients 1, 3 and 5 therefore indicate vagal denervation in a functional sense, but whether the dysfunction was neural or receptor, or both, cannot be stated.

We could not determine whether the parasympathetic dysfunction was paralleled by sympathetic nervous dysfunction in the same patients. However, in contrast to the results of the Portuguese study,[9] we did not find any hyporesponsiveness of the cardiac β adrenoceptors to isoproterenol, which we gave in the double dose. The reactions to propranolol were also as expected. Therefore, dysfunction at the β-adrenoceptor level apparently can be ruled out, although sympathetic neuropathy cannot be excluded.

From the *quantitative* point of view, the dysfunction of autonomic heart regulation in the present group of patients did not play a major role in conduction abnormalities, which were unaffected by pharmacologic intervention except in patient 2, in whom atropine improved atrioventricular nodal conduction. The partially reversible impairment of atrioventricular nodal function in this patient could be a result of increased vagal activity, owing to nervous excitation in analogy with paresthesias, or a result of denervation oversensitivity of the receptors.

The main pathophysiologic mechanism underlying the conduction abnormalities in our patients with FAP apparently is *amyloid infiltration* of the conduction system, in accordance with histopathologic studies.[2,3]

The disease was fairly advanced in all cases. However, the normal findings in regard to vagal function in patient 4 suggest that the vagal function may remain intact

despite fairly advanced cardiac amyloidosis. The same apparently applies to β adrenoceptors.

FAP is a rare disorder, but the combination of myocardial disease and autonomic dysfunction is also found in patients with diabetes mellitus. Therefore, a warning should be extended concerning the interpretation of heart rate reactions in autonomic tests to include diabetic patients. An electrophysiologic study may be required both in patients with FAP and in diabetic patients for assessment of the ability of the cardiac conduction system to respond to different autonomic tests.

Atrial Septal Aneurysm: Echopolycardiographic Study

CARLO LONGHINI, MD, MARIA CRISTIANA BRUNAZZI, MD,
GIANFRANCA MUSACCI, MD, MARZIA CANEVA, MD,
ATTILIO BANDELLO, MD, LORENZO BOLOMINI, MD, MARIO BARBIERO, MD,
TIZIANO TOSELLI, MD, and FRANCO BARBARESI, MD

Atrial septal aneurysm (ASA) with diagnosis during life is a rarely reported anomaly, especially when not associated with other congenital or acquired valvular cardiopathies. Among 4,000 routine echocardiograms, 23 cases of ASA were found (8 men and 14 women, aged 19 to 79 years). Three patients had coronary artery disease, 2 had dilated cardiomyopathy, 2 had systemic hypertension, 11 had mitral valve prolapse and 5 had no other identifiable cardiovascular diseases. Echocardiography revealed various motion patterns of ASA. No phonomechanocardiographic findings were related to the presence of ASA, and no correlation between echographic and phonocardiographic findings was found.

(Am J Cardiol 1985;56:653–656)

Although atrial septal aneurysm (ASA) is a well known morphologic phenomenon,[1] it has been reported as an unexpected finding during autopsy,[1–9] angiographic examinations[10–15] and, more recently, echocardiographic examinations.[16–29] ASA is rarely diagnosed in living patients, particularly when it is not associated with other congenital or acquired valvular cardiopathies. The present report describes the echo-phonocardiographic findings of 23 adult patients with ASA.

Methods

Twenty-three patients among 4,000 consecutive patients examined were found to have ASA by echocardiography. Clinical and instrumental data are listed in Table I. Three patients had coronary artery disease, 2 had dilated cardiomyopathy, 2 had systemic hypertension, 11 had mitral valve prolapse (2 of whom also had systemic hypertension and 2 coronary artery disease) and 5 had no other identifiable cardiovascular diseases. Seven patients who underwent cardiac catheterization had no detectable shunts on oximetry, and in none was a shunt demonstrated by echo contrast. In accordance with Gondi and Nanda,[16] we selected the presence of localized outpouching of the atrial septum as a qualitative definition of ASA; overall bulging of the atrial septum was excluded from our study.[22,30] Until the present study only 1 echographic study has mentioned a quantitative criterion for the amount of bulging necessary to define ASA[29]; we use 0.8 cm as the minimal amount of bulging necessary to define ASA. Our definition was based on the maximal radius of the smallest aneurysm diagnosed by subcostal 2-dimensional echocardiography and confirmed by angiography. The echocardiographic studies were performed using a commercially available sector scanner (Smith Kline Instruments, model 5,000). Patients were examined in both the supine and 30° lateral position (right and left) during quiet respiration, and the heart was visualized using parasternal, apical, subcostal transducer locations. The M-mode echograms of the ASA were recorded both from the right parasternal[31,32] and subcostal views by passing the ultrasound beam through the midportion of the ASA during each cardiac cycle. During our examinations, using the right parasternal view, M-mode recordings of the atrial septum did not always give good quality pictures; conversely, good echograms for motion analysis of the atrial septum were obtained in all cases from the subcostal view. Normal M-mode motion patterns of the atrial septum in published reports have been carried out through the right parasternal view.[31,32] We therefore studied the M-mode subcostal pattern of the atrial septum in normal subjects (Fig. 1). This pattern showed no substantial differences from M-mode curves obtained through the right parasternal approach.[31,32] Contrast echographic studies were performed using Meltzer's method,[33] both to exclude the possibility of a coexisting interatrial shunt and to give a complete morphologic evaluation of the atrial septum. The phonocardiograms and pulse tracings were recorded on a 6-channel ink-jet direct writing recorder (Elema Mingograph 81), with a piezoelectric microphone (EMT 23b), an amplifier (EMT 21)

AMI = acute myocardial infarction; ASI = anteroseptal infarction; AVB = atrioventricular block; CAD = coronary artery disease; DCM = dilated cardiomyopathy; ESC = early systolic click; LAFB = left anterior fascicular block; LBBB = left bundle branch block; LSM = late systolic murmur; LVH = left ventricular hypertrophy; MVP = mitral valve prolapse; NEC = nonejection click; S_3 = third heart sound; S_4 = fourth heart sound; SH = systemic hypertension; SVA = superaventricular arrhythmia; 0 = none.

with different filters (25, 50, 100, 200 and 400 Hz), and an arterial transducer (EMT 439a); the registrations were recorded with the patients in the supine and left recumbent positions, from the 4 standard auscultatory areas, during mild expiratory apnea and during different tests (inspiration, standing, amyl nitrite and Valsalva maneuver).

Results

Echocardiography revealed 3 motion patterns.

Type 1: In 10 patients, the ASA projected into the right atrium during diastole, with early systolic bulging into the left atrium, followed by rightward crossing-over motion in midsystole. This motion pattern appeared both during inspiration and expiration (Fig. 2, top and 3A).

Type 2: In 6 patients, ASA presented a sustained right deviation during expiration; a leftward motion occurred only during inspiration in early ventricular systole (Fig. 2, middle and 3B).

Type 3: In 7 patients, ASA remained in the right atrium, with an undulating motion during all the phases of cardiac and respiratory cycles. This type of M-mode recording results because the aneurysm is motionless except for imperceptible ripples of the wall (Fig. 2, bottom, 3C and 4).

Phonomechanocardiography showed: (1) A nonejection click in 11 patients, all with mitral valve prolapse (MVP). Four patients also had late systolic murmur. The effect of physiologic postural and pharmacologic intervention on the click and murmur yielded reproducible results in a given patient. During inspiration, standing and inhalation of amyl nitrite, the systolic click and onset of the murmur tended to move toward the first heart sound. During the overshoot

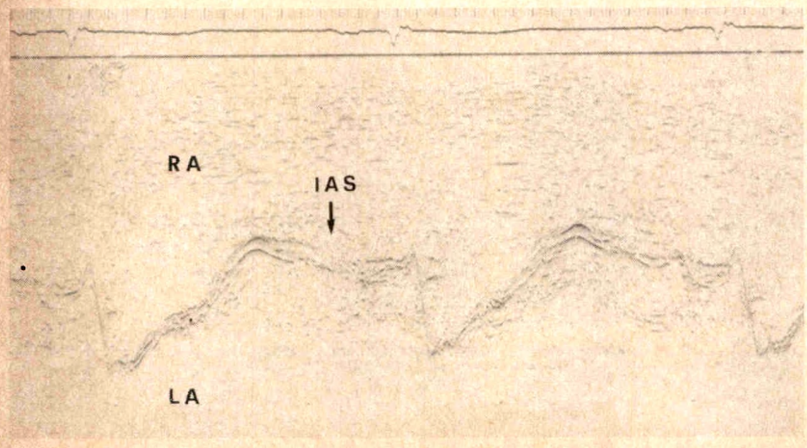

FIGURE 1. Normal M-mode pattern of the atrial septum (subcostal view). The atrial septum projects into the left atrium during early ventricular systole, and it returns toward the right atrium in midsystole. IAS = interatrial septum; LA = left atrium; RA = right atrium.

phase of the Valsalva maneuver the click and onset of the murmur were delayed. (2) Early systolic click, synchronous with the beginning of the carotid pulse upstroke in 2 patients (1 with MVP and 1 with systemic hypertension). (3) Third (S_3) and/or fourth (S_4) heart sounds in 3 patients (1 with heart failure and 2 with idiopathic dilated cardiomyopathy). (4) Carotid and jugular pulses that were unremarkable except in 1 patient (no. 3) whose ratio between preejection period and left ventricular ejection time was slightly increased.

Discussion

ASA has been reported in patients with associated congenital or acquired valvular cardiopathies, and is usually accompanied by an increased intraatrial pressure,[4–6,11–13,16,17,21,23,24] and in those without heart defects by normal intraatrial pressure.[1–3,7,8,10,14,15,18,20,22,25–29] Echocardiography makes it possible to detect this anomaly much more frequently during life (even in patients without other cardiopathies) than in the past, when diagnosis was possible

only using angiographic studies.[10] Because these patients may be at risk (pulmonary or systemic emboli, obstruction of either tricuspid or mitral valve, pulmonary venous obstruction),[10,12,15,17,29] the diagnosis of ASA is important. We believed it important to verify in our patients the presence of any phonomechanocardiographic findings related to ASA, as previously, signaled in 1 case of Don Alexander et al.[18] From our study the following conclusive points emerge: (1) No phonomechanocardiographic findings were related to the presence of ASA; in particular the nonejection systolic click was found only in patients with MVP and the response of the click to various maneuvers was typical of MVP.[18,20,34,35] The other phonocardiographic findings (ejection click, S_3 and S_4) were explained by the associated cardiovascular pathology. (2) Echocardiographic findings revealed polymorphic motion patterns of ASA (the same conclusion can be reached by careful analysis of single reported cases).[18,20,24] No specific factors responsible for these different echographic patterns, such as cavity dilation or increased intracavitary pressure, were identified. We maintain that 2-dimensional echocardiography permits both a clear identification of ASA and a good evaluation of its motion patterns; in contrast, M-mode curves show neither constant nor specific patterns of ASA. (3) No correlations were found between the different echographic patterns and phonocardiographic findings in single cases.

"When the Ayerst rep told me it costs about 45¢ a day, I said you can stop right there."

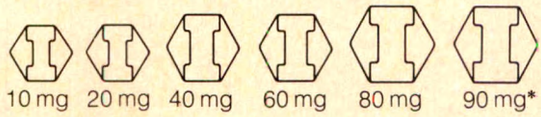
Most doctors are pleasantly surprised to learn that the average cost of daily therapy with the world's most widely used beta blocker is so little, not much more than the cost of a daily newspaper.

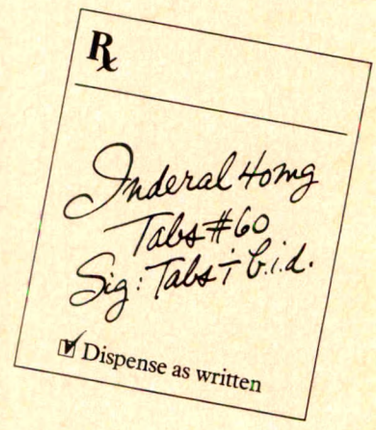
When it's INDERAL (propranolol hydrochloride) tablets you want for your hypertension patients, remember to specify Dispense As Written (DAW) or Do Not Substitute on your prescriptions. That way, you can always be assured they'll get INDERAL®. Please see next page for brief summary of prescribing information.

INDERAL®
(PROPRANOLOL HCl)
Small price to pay.

"When the Ayerst rep told me it costs about 45¢ a day, I said you can stop right there."

INDERAL® TABLETS
(PROPRANOLOL HCl)





BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)

INDERAL® (propranolol hydrochloride) Tablets

CONTRAINDICATIONS

INDERAL is contraindicated in 1) cardiogenic shock, 2) sinus bradycardia and greater than first degree block, 3) bronchial asthma, 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

• DIABETES AND HYPOGLYCEMIA: Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS: Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS

General: Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta-adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL (propranolol hydrochloride) may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose.

There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; thrombocytopenic purpura; arterial insufficiency, usually of the Raynaud type.

Central Nervous System: Lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.

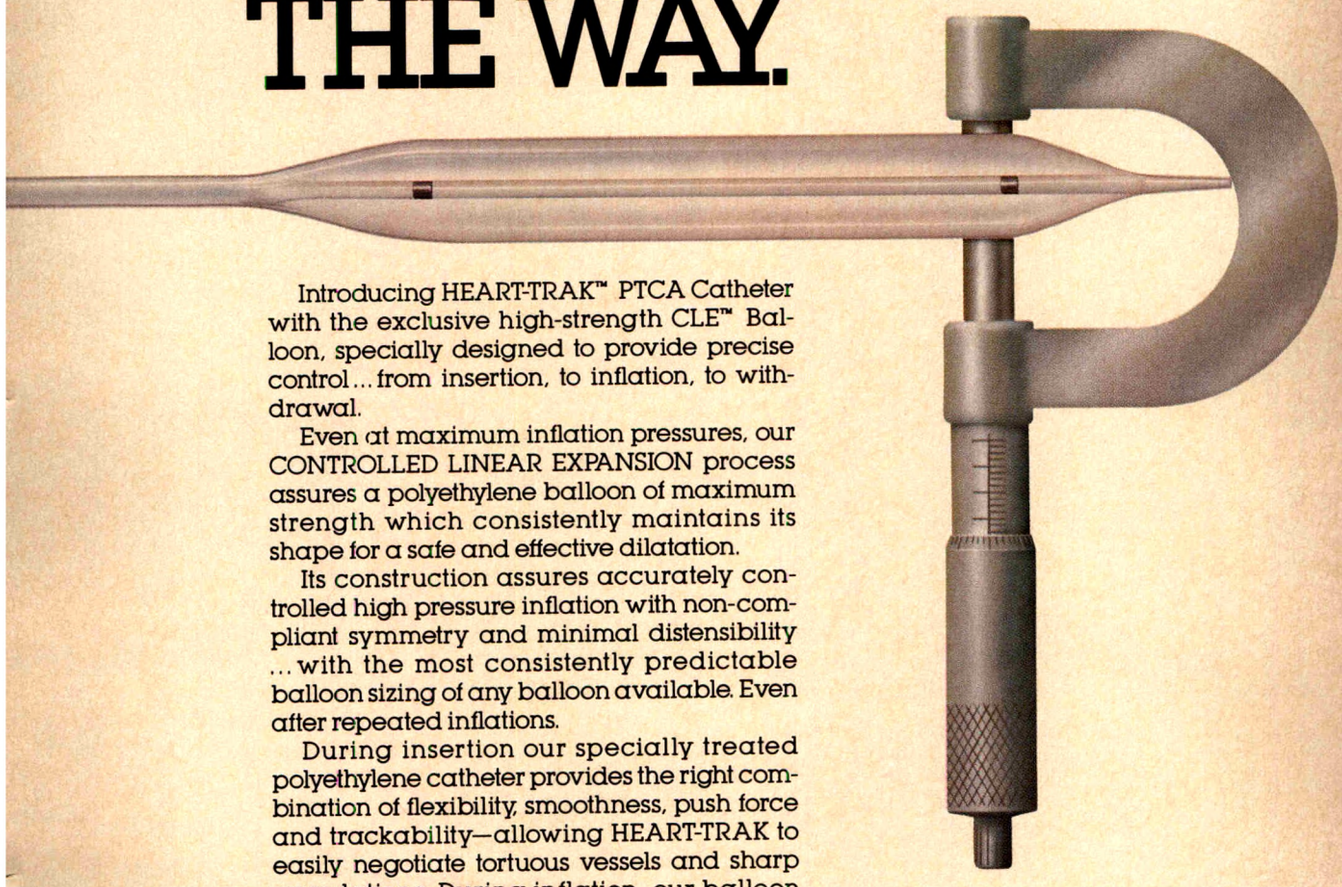
CONTROL. EVERY STEP OF THE WAY.



Introducing HEART-TRAK™ PTCA Catheter with the exclusive high-strength CLE™ Balloon, specially designed to provide precise control... from insertion, to inflation, to withdrawal.

Even at maximum inflation pressures, our CONTROLLED LINEAR EXPANSION process assures a polyethylene balloon of maximum strength which consistently maintains its shape for a safe and effective dilatation.

Its construction assures accurately controlled high pressure inflation with non-compliant symmetry and minimal distensibility ... with the most consistently predictable balloon sizing of any balloon available. Even after repeated inflations.

During insertion our specially treated polyethylene catheter provides the right combination of flexibility, smoothness, push force and trackability—allowing HEART-TRAK to easily negotiate tortuous vessels and sharp angulations. During inflation, our balloon gives you the confidence that the vessel will be dilated effectively and safely.

HEART-TRAK™ PTCA CATHETER

Confidence in the most critical cases

Reliquary, for the heart of Anne of Brittany
Museum of Nantes

Crafted entirely in gold, the reliquary bears an eloquent inscription extolling the virtue of Anne, Duchess of Brittany and Queen of France. The reliquary dates from 1513.

dipyridamole Tablets of 25, 50 and 75 mg

Persantine®

The experienced dipyridamole

BRIEF SUMMARY

INDICATIONS—Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indication as follows:
"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency of, or eliminate, anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack. Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.
PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.
ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.
DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy. Tablets of 25, 50 and 75 mg. For complete details, please see the full prescribing information.

INFECTIOUS COMPLICATIONS OF NEOPLASTIC DISEASE

Controversies in Management

Edited by Arthur E. Brown, MD, and Donald Armstrong, MD
0-914316-43-5, approx. 400 pp., Oct. 1984, $40.00 casebound

About the book

Derived from a symposium sponsored by the Infectious Disease Service, Department of Medicine and the Department of Pediatrics, Memorial Sloan-Kettering Cancer Center, New York City, and Cornell University Medical College, New York City, this book presents the latest thinking by international authorities, all of whom were invited to present findings in their area of expertise on the diagnosis, treatment, and prevention of various bacterial, fungal, viral, and parasitic infections presenting in patients with neoplastic disease.

This is not just another "proceedings" volume. Rather it is an edited work, with papers by investigators who submitted definitive preparations for publication. Furthermore, the authors take a strong position on their topics, ask probing questions and promote a stimulating forum of controversy.

The result is a concise, dynamic study that belongs in the professional library of every physician treating patients with neoplastic disease.

About the Editors

Arthur E. Brown, MD, is Assistant Attending Physician, Memorial Sloan-Kettering Cancer Center, and Assistant Professor of Medicine and Pediatrics, Cornell University Medical College.

Donald Armstrong, MD, is Attending Physician; Chief of Service; Director, Microbiology Laboratory, Memorial Sloan-Kettering Cancer Center, and Professor of Medicine, Cornell University Medical College

Table of Contents

PART I. DIAGNOSIS AND TREATMENT

Introduction and epidemiology
Neutropenia, fever, and infection
Significance of serum bactericidal activity in gram-negative bacillary bacteremia in patients with and without granulocytopenia
Approaching the controversies in antibacterial management of cancer patients
Can antibacterial therapy be discontinued in persistently febrile granulocytopenic cancer patients?
Quantitative blood cultures: a review of 52 years
Opportunistic fungal infections in patients with neoplastic disease
Chemotherapy of Systemic Mycoses
Viral infections in patients with neoplastic disease: diagnosis and therapy
Parasitic diseases in immunocompromised hosts

PART II. AIDS

Cluster of cases of the acquired immune deficiency syndrome: patients linked by sexual contact
Model-based approach to an analysis of a cluster pattern
Association between acquired immune deficiency syndrome and sexual contact: an analysis of the incidence pattern
Acquired immune deficiency syndrome (AIDS) trends in the United States
Assessment of therapy for Pneumocystis carinii pneumonia PCP Therapy Project Group

PART III. PREVENTION

Granulocyte transfusions
Leukocyte transfusions: thinking twice
Chemoprophylaxis of bacterial infections in granulocytopenic patients
Chemoprophylaxis of fungal infections
Legionnaires' Disease: aspects of nosocomial infection
Immunoprophylaxis and serotherapy of bacterial infections
Immunoprophylaxis of varicella-zoster infections
Current status of prophylaxis of infection with protected environments
Protected environments are discomforting and expensive and do not offer meaningful protection

Clinical Clues to MIXED ANGINA *No. 5*

The stairs seem steeper today

Most days she can climb the stairs with no difficulty. But today she was less than half-way up when an angina attack stopped her.

That's the unpredictability of MIXED ANGINA—vasoconstriction coexisting with fixed coronary lesion, to produce a critical reduction of myocardial blood flow.

And because vasoconstriction is an unpredictable event, ischemia and pain occur unpredictably:

- at varying levels of exercise
- at rest, or even during sleep
- upon exposure to cold
- under emotional stress
- diurnally, typically in the morning

PROCARDIA® (nifedipine) is a primary therapy for the patient with MIXED ANGINA. It prevents vasoconstriction in both large coronary arteries and coronary arterioles to maintain myocardial blood flow and oxygen supply. At the same time, PROCARDIA dilates peripheral arteries to reduce afterload and myocardial oxygen demand.

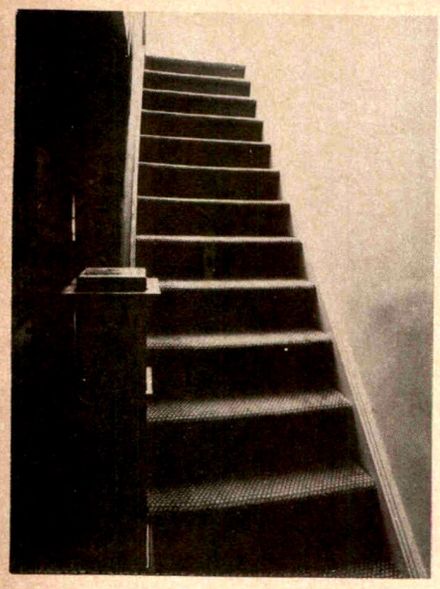
As a result, PROCARDIA can significantly reduce your patient's angina attack rate and need for nitroglycerin.[1]

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

Primary Protection in
MIXED ANGINA

Please see PROCARDIA® (nifedipine) brief summary on next page.

The stairs seem steeper today



PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

PRIMARY PROTECTION IN MIXED ANGINA

Usual Effective Dosage: 30 to 60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because PROCARDIA decreases peripheral vascular resistance (occasional patients have had excessive hypotension), careful monitoring of blood pressure during initial administration and upward dosage titration is suggested, especially for patients taking drugs known to lower blood pressure. Occasional patients have developed increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases.

A Favorable Safety Profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

1. Stone PH, Muller JE, Turi ZG, et al: Efficacy of nifedipine therapy in patients with refractory angina pectoris: Significance of the presence of coronary vasospasm. *Am Heart J* 106:644-652, 1983.

Brief Summary
PROCARDIA® (nifedipine) Capsules For Oral Use

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See WARNINGS.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina: Occasional patients have developed well-documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See WARNINGS.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Laboratory tests: Rare, usually transient, but occasionally significant elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT and SGPT have been noted. The relationship to PROCARDIA (nifedipine) therapy is uncertain in most cases, but probable in some. These laboratory abnormalities have rarely been associated with clinical symptoms, however, cholestasis with or without jaundice has been reported. Rare instances of allergic hepatitis have been reported.

Limited clinical studies have demonstrated a moderate but statistically significant decrease in platelet aggregation and increase in bleeding time in some PROCARDIA patients. No clinical significance for these findings has been demonstrated.

Although PROCARDIA has been used safely in patients with renal dysfunction and has been reported to exert a beneficial effect in certain cases, rare, reversible elevations in BUN and serum creatinine have been reported in patients with pre-existing chronic renal insufficiency. The relationship to PROCARDIA therapy is uncertain in most cases but probable in some.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Coumarin anticoagulants: There have been rare reports of increased prothrombin time in patients taking coumarin anticoagulants to whom PROCARDIA was administered.

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak nifedipine plasma levels (80%) and area-under-the-curve (74%) after a one week course of cimetidine at 1000 mg per day and nifedipine at 40 mg per day. Ranitidine produced smaller, non-significant increases. If nifedipine therapy is initiated in a patient currently receiving cimetidine, cautious titration is advised.

Carcinogenesis, mutagenesis, impairment of fertility: Nifedipine was administered orally to rats for two years and was not shown to be carcinogenic. When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose. *In vivo* mutagenicity studies were negative.

Pregnancy: Pregnancy Category C. Nifedipine has been shown to be teratogenic in rats and embryotoxic in rats, mice and rabbits. There are no adequate and well controlled studies in pregnant women. PROCARDIA should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: The most common adverse events include dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, shortness of breath, diarrhea, constipation, gastrointestinal cramps, flatulence, inflammation, joint stiffness, shakiness, jitteriness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, sexual difficulties, thrombocytopenia, anemia, leukopenia, purpura, allergic hepatitis, gingival hyperplasia, and erythromelalgia. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

HOW SUPPLIED: Each orange soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

Measurement of Cardiac Output by Cine Computed Tomography

JEFFREY S. GARRETT, MD, PETER LANZER, MD, WERNER JASCHKE, MD, ELIAS BOTVINICK, MD, RICHARD SIEVERS, BS, CHARLES B. HIGGINS, MD, and MARTIN J. LIPTON, MD

High-speed computed transmission tomography (cine CT) is a new noninvasive technique that may be useful for the rapid, accurate quantitation of cardiac function. The capability of cine CT to assess cardiac output was examined 10 mongrel dogs as an initial step in validating this method. After the dogs were anesthetized, femoral arterial pressure and pulmonary artery thermodilution catheters were inserted. After intravenous injection of a bolus of contrast medium, cine CT scans were performed in the flow mode, in which 50-ms scans were triggered electrocardiographically at end-diastole at 8 levels during sequential cardiac cycles. Scans and thermodilution measurements of cardiac output were obtained at rest and during altered hemodynamic states induced by separate infusions of dobutamine and phenylephrine. Time-density analysis was performed over the left ventricular cavity and curves were fitted to the CT flow data by gamma-variate analysis. Using the Stewart-Hamilton equation established for indicator dilution techniques, the cardiac output was calculated. The results established a direct linear correlation (r = 0.92) between cine CT cardiac output and thermodilution cardiac output over a wide range of cardiac outputs (1.5 to 6.3 liters/min). This study demonstrates that cine CT can provide a reliable estimate of cardiac output noninvasively using contrast medium as an indicator in dogs.

(Am J Cardiol 1985;56:657–661)

Measurement of cardiac output is the most accurate way of assessing overall cardiovascular performance. Until recently, rapid, accurate measurement of cardiac output has not been possible using noninvasive techniques. The present investigation was designed to assess the ability of an ultra-fast, new-generation, computed axial tomographic (cine CT) scanner to measure cardiac output in dogs over a wide range of values using an indicator dilution technique.

From the Departments of Radiology and Medicine (Cardiovascular Division) and Cardiovascular Research Institute, University of California, San Francisco, California. This work was supported in part by Research Grant 1 R01 33424-01 from the National Institutes of Health, Bethesda, Maryland, and grants from the Fannie Ripple Foundation, Madison, New Jersey, the Radiology Research and Education Foundation, San Francisco, California, and Imatron, Inc., South San Francisco, California. Dr. Garrett is a recipient of Individual Research Fellowship HL-06944 from the National Institutes of Health. Dr. Botvinick is a recipient of an Established Investigator Award of the American Heart Association, Dallas, Texas, with funds contributed by local Heart Associations, and is supported in part by the George D. Smith Fund, San Francisco, California. Manuscript received February 13, 1985; revised manuscript received April 26, 1985, accepted April 30, 1985.

Address for reprints: Martin J. Lipton, MD, University of California, San Francisco School of Medicine, C-309, San Francisco, California 94143.

Indicator dilution techniques have been used since 1897 to evaluate blood flow. Stewart[1] introduced the basic theory, which was further developed by Hamilton et al[2] and applied to the measurement of cardiac output.[3] Thermodilution and hydrogen indicator dilution techniques are widely used and have emerged as practical and reproducible. Contrast medium is an alternative indicator that may be used to assess cardiac output provided that continuous sampling of the indicator is possible to determine density (concentration) vs time. This study was performed to determine whether the rapid, repeated densitometric measurements obtained with the use of a noninvasive CT technique can permit the accurate assessment of cardiac output while simultaneously providing structural cardiac detail.

Methods

Ten mongrel dogs (28 to 32 kg) were anesthetized with sodium pentobarbitol (25 mg/kg) and Innovar® (10 mg/kg) and intubated. Respiration was maintained and controlled at 16 breaths/min with a Harvard pump respirator. Continuous pressure monitoring was performed with a catheter inserted into the femoral artery. A Swan-Ganz thermodilution catheter

was inserted through the femoral vein and advanced into the pulmonary artery and a separate venous catheter was inserted and advanced to the midportion of the inferior vena cava. Electrocardiograms were continuously monitored and recorded during scanning. Cardiac output was measured by thermodilution using an Edwards cardiac output computer and from measurements made during simultaneous CT scanning. Measurements were performed in the control state, before pharmacologic intervention, and after sequential 20-minute infusions of dobutamine (10 μg/kg/min) and phenylephrine (0.025/mg/kg/min).

CT scanning was performed on the first production fast (cine) CT scanner[4] (Imatron, Inc.). The cine CT scanner design incorporates an electron beam, which replaces the heavy,

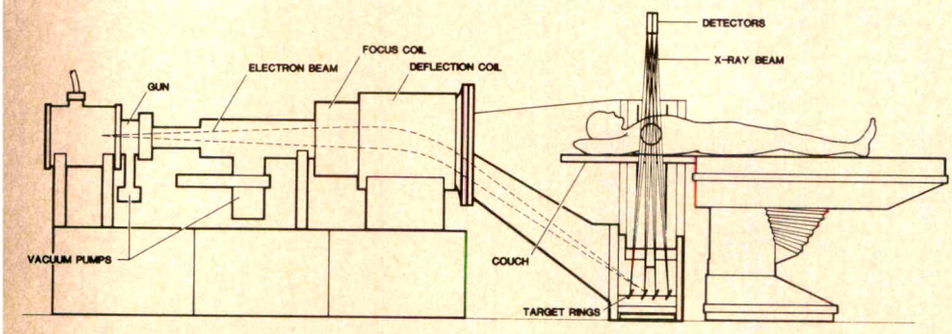

FIGURE 1. Imatron C-100 scanner. An x-ray fan is produced when an electron beam, focused by a magnetic field is swept along tungsten target rings.

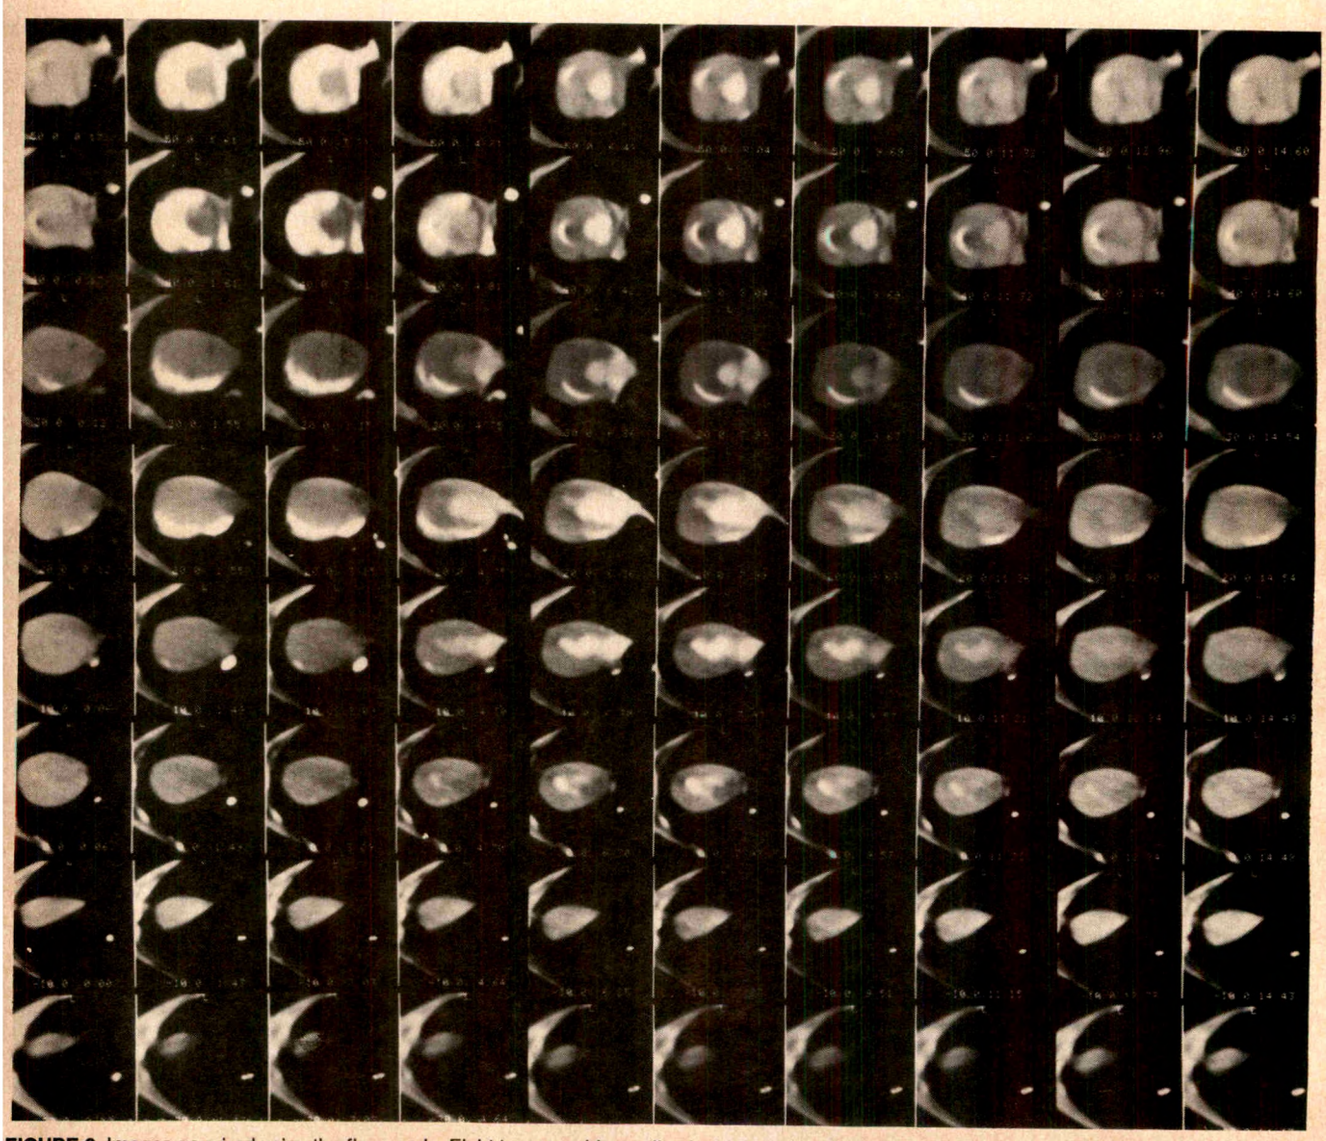

FIGURE 2. Images acquired using the flow mode. Eight tomographic cardiac levels are displayed. The bolus is observed passing sequentially from the right to left side of the heart. The entire series of images displayed was obtained in under 20 seconds.

rotating x-ray tube present in whole-body CT scanners. The electron beam is bent and focused by a magnetic field and acquires as many as eight 1-cm-thick tomographic levels simultaneously (Fig. 1). The scan exposure time is 50 ms. All images were acquired in this study during full inspiration with the dog in the right lateral position on the scanning table. Scan acquisition was electrocardiographically triggered at 80% of the averaged length of the proceeding 7 RR intervals, so that all scans for successive cardiac cycles were acquired in diastole.

Scans were acquired for approximately 20 seconds after the intravenous administration of a 10-ml bolus of iothalamate sodium (Conray 400) (Fig. 2). Time-density analysis was performed over a left ventricular region of interest and curves were fitted to the CT flow data by a least-squares gamma-variate analysis,[5] thus correcting for recirculation. This was done at 3 ventricular levels and the areas under these curves were obtained. Thermodilution measurements were performed in triplicate. Intracavitary regions of interest were manually defined over the ventricle. The hypothesis that the areas obtained by the time-density analysis at each of the 3 ventricular levels were the same, was tested by repeated measures analysis of variance using the following regression model:

$$\text{Area} = A + B(L1) + C(L2) \quad (1)$$

where AREA = area obtained by the time-density analysis, A, B, C = regression coefficient and L1 and L2 = dummy independent variables representing the 3 ventricular levels. L1 was defined at 1 for level 1, 0 for level 2 and −1 for level 3 and L2 was defined as 0 for level 1, 1 for level 2, and −1 for level 3.[6] F was calculated as

$$\frac{\text{Mean sum of squares regression}}{\text{mean sum of squares residual}} \quad (2)$$

and was evaluated at the 0.05 level.

Cardiac output was calculated using the standard Stewart-Hamilton[3] equation:

$$CO = X/c(t)dt \quad (3)$$

where CO = cardiac output, X = quantity of indicator injected into the system and c(t) = concentration at the sampling site at time t. This concentration value may be modified to account for the measurement of the contrast density instead of absolute concentration, provided that there is a linear relation between indicator (iodine) concentration and CT number over the range of the study. Equation 3 therefore becomes

$$CO = (X)(A)/D(t)dt \quad (4)$$

where D(t) = density in CT numbers at the sampling site at time t and A = constant of proportionality relating c(t) to D(t). If a constant sized bolus of indicator is used, the equation then becomes

$$CO = K/D(t)dt. \quad (5)$$

Equation 5 may therefore be applied to the measurement of cardiac ouput, provided the following conditions are met: (1) The contrast indicator must have the same distribution of transit times as that of the blood. (2) Recirculation phase of the indicator is excluded prior to computing the cardiac output. (3) All of the contrast medium eventually leaves the heart. (4) Cardiac output is not changing while the measurement is being made. (5) Negligible contrast medium is lost during transit through the lungs.[7]

The densitometric system used to measure indicator concentration was validated in phantom experiments. A water phantom measuring 31 cm in diameter was constructed of Plexiglas®. The phantom contained a peripherally placed hollow core (4.5 cm diameter) (Fig. 3). The core was filled with a range of concentrations of standard iothalamate sodium contrast medium (0 to 38 mg iodine/ml) to approximate the concentration of the diluted bolus at the cardiac level. These phantoms were scanned and cine CT densitometric measurements were performed.

Results

The accuracy of indicator dilution techniques relies on the ability to precisely measure indicator concentration. Phantom measurements demonstrated linearity of CT number vs indicator concentration over the density range considered in this study with a correlation coefficient of 0.99 (Fig. 4).

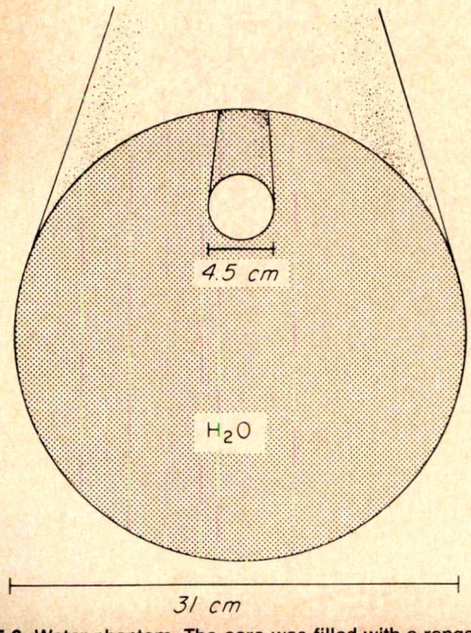

FIGURE 3. Water phantom. The core was filled with a range of concentrations of contrast medium and the phantom was scanned to verify the relationship between CT density and absolute concentration.

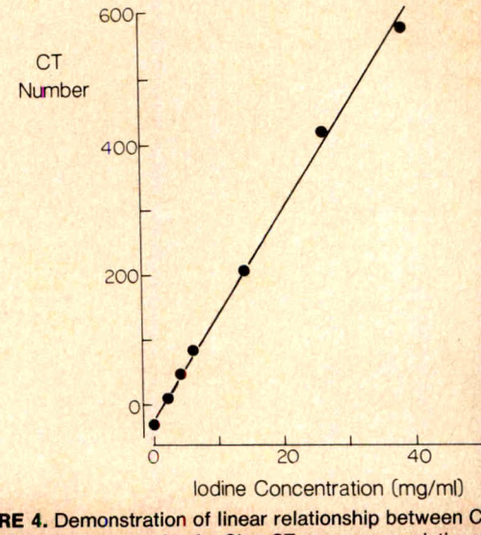

FIGURE 4. Demonstration of linear relationship between CT number and indicator concentration for Cine-CT scanner correlation coefficient (R)-0.99.

Figure 5 represents a typical time-density analysis used to quantitate cardiac output in a dog. Once a region of interest over the ventricular cavity was selected, the mean CT number for that region was automatically plotted for each sequential scan vs lapsed time from onset of injection. The cine CT scanner performed this analysis on line within 1 to 2 seconds. The gamma-variate fit was then superimposed on the individual measurements, and the area under the curve was calculated and displayed on the cathode ray viewing screen.

The regression model (equations 1 and 2) was applied to test for the interlevel variability of the area. F was equal to 0.16 ($p < 0.05$) thus, demonstrating that no significant interlevel variability was present.

K (equation 5) was calculated from the slope of the CT density-iodine concentration relation (Fig. 4). There was high correlation ($r = 0.92$) for cine CT–determined cardiac output and thermodilution cardiac output over a wide range of cardiac outputs (1.5 to 6.3 liters/min) (Fig. 6).

Discussion

Many techniques are available to assess cardiac output, including thermodilution, oxygen consumption, nuclear and Doppler methods.[8] Conventional CT scanners may be used to assess cardiac output[9]; however, they have a limited role in cardiac diagnosis. The major problems of conventional CT scanners is the relatively long exposure time of 1 to 5 seconds compared with the length of the cardiac cycle. This is compounded by the long interscan delay time and single slice configuration.

The cine CT scanner uses a revolutionary solution to these problems and makes possible the simultaneous evaluation of structure and function. Cine CT scanning is a digital tomographic technique that minimizes the problem of misinterpretation due to overlying structures inherent in traditional cardiac radiographic techniques and provides outstanding spatial resolution at multiple cardiac levels. We have demonstrated that it is possible to acquire noninvasively an indicator (density) curve over time using a cine CT scanner and a small amount of peripherally administered contrast medium. This information may then be used to accurately assess the cardiac output. Because this curve is, in fact, generated from densitometry of discrete images, anatomic measurements at multiple tomographic levels may be made from images obtained with a single bolus injection.

The time-density analysis technique for the measurement of cardiac output assumes that the selected region of interest from which the time-density data is compiled is always either intravascular or intracavitary, and the number of pixels included in the region of interest are maximized so that sampling error is minimized. If the selected region of interest is not reproducibly intravascular or intracavitary (i.e., the vessel or cavity has moved away from the selected region), then an error occurs, which is termed "partial volume effect." The partial volume effect results from the sampling of pixels on serial images that are geometrically but not anatomically identical. We have found that intracavitary regions of interest minimizes partial volume effects while maximizing the number of pixels sampled. Left ventricular regions of interest are especially suited to cardiac output determinations because this is the site of the most complete mixing of the contrast agent with the blood pool.

Contrast medium has hemodynamic effects which may alter the determination of of cardiac output by cine CT.[10] It may be possible to eliminate this potential source of error by using nonionic contrast agents. Possible hemodynamic effects of contrast media on the determination of cardiac output were not severe enough

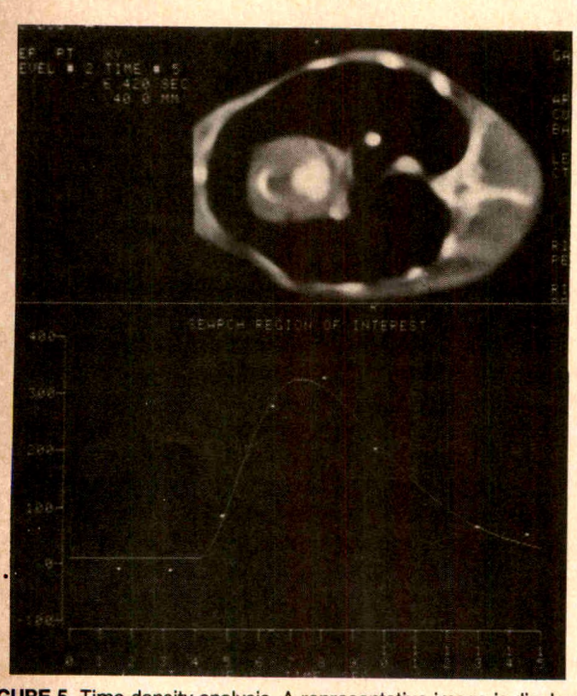

FIGURE 5. Time-density analysis. A representative image is displayed with a region of interest defined over the left ventricle (above). CT density is plotted vs time (below) and the gamma variate fit is superimposed.

in the current study to vitiate the close correlation between CT and thermodilution measurements.

If images are acquired at the maximum rate of 17 scans/s (50 ms/scan), regional myocardial wall thickening can also be evaluated because CT displays both the endocardial and epicardial walls.[11] The indicator dilution technique for cine CT described in this report applied in conjunction with the advanced graphics capabilities of the scanner's computer can also provide documentation and quantification of intracardiac shunts. The precision of such measurements remains to be determined and validated. Cine CT is a new technique for cardiologic diagnosis with a unique potential for qualitative and quantitative analysis of anatomic variables of ventricular function while noninvasively evaluating physiologic variables during the same procedure.

Reduction of Laser-Induced Pathologic Tissue Injury Using Pulsed Energy Delivery

LAWRENCE I. DECKELBAUM, MD, JEFFREY M. ISNER, MD,
ROBERTA FORTIN DONALDSON, BS, RICHARD H. CLARKE, PhD,
SYLVIE LALIBERTE, BS, ALON S. AHARON, BS, and JEFFREY S. BERNSTEIN, BS

Continuous-wave (CW) laser irradiation of cardiovascular tissues is characterized by 2 distinctive histologic findings: a superficial zone of coagulation necrosis and a subjacent zone of polymorphous lacunae. The present investigation was designed to determine whether such injury could be eliminated by altering the temporal profile of laser energy delivery. One hundred forty-five myocardial slices were irradiated with an air-tissue interface using CW laser irradiation at wavelengths of 488 to 515 nm (argon), 1,064 nm (Nd-YAG) and 10,600 nm (CO_2). Pulsed laser irradiation included 248 nm (excimer); 355, 532 and 1,064 nm (Nd-YAG); and 515 nm (mode-locked argon). Energy profiles in the pulsed mode included a range of repetition rates (1 Hz to 256 MHz), pulse duration (0.2 to 358 ns) and pulse energies (2 nJ to 370 mJ). Resultant average powers were 0.1 to 38 W. Grossly visible charring of myocardial tissue was observed at all laser wavelengths when the laser energy profile was CW or pulsed at high repetition rates (more than 2 KHz) and low pulse energies (less than 3 mJ) independent of the wavelengths used. In contrast, when laser energy was pulsed at low repetition rates (less than 200 Hz) and large pulse energies (more than 10 mJ), neither gross nor histologic signs of thermal injury were observed.

Pathologic injury associated with laser-induced tissue ablation may thus be substantially reduced by use of pulsed energy delivery at low repetition rates. Potential advantages of pulsed laser energy include a more benign healing process, a less thrombogenic surface, and improved preservation of structural tissue integrity.

(Am J Cardiol 1985;56:662–667)

Previous investigations[1–9] have established the potential utility of laser irradiation in the treatment of cardiovascular disorders. Previous studies have also shown that continuous-wave (CW) laser irradiation of cardiovascular tissues is characterized by 2 distinctive histologic findings: a superficial zone of coagulation necrosis and a subjacent zone of polymorphous lacunae. The former has been attributed to thermal injury,[3,10–12] whereas the latter has been interpreted to result from "acoustic" or "shock" injury.[12,13]

Laser energy can be delivered in a time-varying fashion that is characterized by the laser energy profile, a profile of power output over time. CW lasers have a power output that is constant over time. In contrast, pulsed lasers deliver energy in brief, discrete pulses, each of which is separated by an emission-free interval. There are at least 2 reasons why laser irradiation delivered in the pulsed mode may be expected to cause less damage to tissues adjacent to the target site: If the period of absent energy transmission between pulses is long enough, heat generated during the pulsed emissions might be expeditiously dissipated, preventing thermal tissue damage; alternatively, the higher peak powers characteristic of pulsed lasers may result in a large photon density sufficient to ablate tissue by a nonthermal mechanism.

Accordingly, the present study was designed to determine whether the extent of pathologic injury resulting from laser irradiation of cardiovascular tissue could be reduced by alterations in laser energy profile.

Methods

Tissue: Slices of myocardium obtained in the fresh state from human cadavers or laboratory dogs were used for all experiments. Myocardium was selected on the basis that a standardized preparation—in this case homogeneous tissue with a uniform slice thickness of 0.5 cm—was required to provide a meaningful comparison among various laser wavelengths and energy profiles. Furthermore, studies both in our laboratory[7,8,14] and in other laboratories[3,15] have consistently shown that histologic alterations resulting from laser irradiation are not tissue-dependent; i.e., for a given wavelength and energy profile, laser irradiation of myocardium, atherosclerotic coronary arteries, and calcified aortic valve leaflets produces similar histopathologic changes in all 3 tissues.

Lasers: *CW lasers* used in this study included an argon laser (Coherent, Inc.) a carbon dioxide (CO_2) laser (Cavitron,

Inc.), and a neodymium:yttrium, aluminum, garnet (Nd-YAG) laser (Biolase, Inc.). *Pulsed lasers* included an argon laser (Spectra Physics), 2 krypton fluoride excimer lasers (Lambda Physik, Questek, Inc.) and 2 Ng-YAG lasers (Quantel International, Quantronix Corp). The argon lasers and the CW Nd-YAG laser were coupled to a flexible silica fiber, 200 to 600 μ in diameter. The fiber was positioned approximately 0.5 mm above the myocardial tissue to yield an incident spot size of 0.5 to 1 mm^2. The CW CO_2 laser and the pulsed lasers other than argon emitted an energy beam that was directly incident on the myocardial slice or that was focused through a lens onto the tissue. Incident spot size of the unfocused beam was 0.8 mm^2. Incident spot size of the focused beam was approximately 0.2 mm^2.

All myocardial specimens were irradiated with an air-tissue interface on an optical stage. The endpoint for laser irradiation was the time required to bore through the 0.5-cm-thick specimen and was detected using either a light meter or photosensitive paper placed underneath the tissue.

Average power delivery (in watts) was verified with an external laser power meter (Coherent, Inc.). Repetition rate, i.e., the number of pulses per second in hertz, and pulse duration were predetermined. Pulse amplitude (in joules) was calculated as average power divided by repetition rate. Peak power (in watts) was calculated as pulse amplitude divided by pulse duration.

Analysis of tissue injury: Each specimen was examined in the fresh state, immediately after completion of laser irradiation, for gross evidence of tissue charring, defined as gross blackening or apparent carbonization at the perimeter of the tissue crater; the gross appearance of selected specimens was documented by macrophotography. The specimen was then cut into divided halves, parallel or perpendicular to the laser-irradiated surface, processed routinely for light microscopic examination, and stained with hematoxylin-eosin and Gomori's trichrome stain.

The remaining half of the specimen was prepared for scanning electron microscopy with principal fixation in 0.1 *M* cacodylate-buffered 3% glutaraldehyde (pH 7.3), postfixed with 0.1 *M* cacodylate buffered 1% osmium tetroxide (pH 7.3), washed and dehydrated. After critical point drying, the specimen was coated with gold-palladium (40:60) and examined using an AMRAY-1,000 scanning electron microscope.

Results

A total of 145 slices of myocardium, 0.5 cm thick, were irradiated using an air-tissue interface. The lasers used, details of the energy profile, and the presence or absence of tissue charring are summarized in Tables I (CW) and II (pulsed lasers).

Continuous-wave lasers (Table I, Fig. 1): *Argon laser:* Gross tissue charring was observed in each specimen. Light microscopic examination (Fig. 1) consis-

tently disclosed a superficial zone of coagulation necrosis and a subjacent zone of polymorphous lacunae. Scanning electron microscopy (Fig. 1) confirmed the histologic findings: a superficial coagulum covered an extensive network of lacunae, which along the walls of the trough ranged from 13 to 36 μ.

Nd-YAG: Gross tissue charring was observed in each specimen (Fig. 1). Light microscopic and ultrastructural findings were identical to those observed with CW argon and CO_2.

CO_2 laser: Gross tissue charring was observed in each specimen. Light microscopic and ultrastructural findings were identical to those observed with CW argon.

Pulsed lasers with high repetition rate (Table II) (Fig. 2): *Argon laser:* Gross, light microscopic (Fig. 2) and ultrastructural (Fig. 2) findings in each case were similar to those observed with CW argon.

Nd-YAG: Specimens were irradiated with 532 and 1,064 nm at 2 to 10 kHz. Gross, light microscopic and ultrastructural findings in each case were similar to those observed for pulsed argon.

Pulsed lasers with low repetition rate (Table II, Fig. 3): *Excimer:* Gross evidence of tissue charring was not observed in any specimen. Light microscopy in some cases disclosed no alteration of the residual laser-irradiated tissue; in other cases (Fig. 3), discontinuous linear discoloration (basophilic with hematoxylin and eosin; magentoid with trichrome stain) at the perimeter of the laser crater was observed. Scanning microscopy (Fig. 3) indicated that this light microscopic finding corresponded to "wrinkling" or "pruning" of the myocytes directly adjacent to the laser crater. Rare, sparsely distributed lacunae were seen.

Nd-YAG: Specimens were irradiated with 355, 533, and 1,064 nm at 2 to 10 Hz. Gross tissue charring was not observed in any specimen. Light microscopic and ultrastructural findings were qualitatively and quantitatively similar to those observed with the excimer laser.

In summary, grossly visible charring of myocardial tissue was observed at all laser wavelengths when the laser energy profile was continuous or pulsed at high repetition rates (higher than 2 kHz) with low pulse energies (less than 3 mJ). Charring was absent when laser irradiation was delivered in the pulsed mode at low repetition rates (less than 200 Hz) with high pulse energies (more than 10 mJ), independent of the wavelengths used. Tissue charring observed on gross examination consistently was associated with light microscopic findings of coagulation necrosis and polymorphous lacunae. In the absence of gross tissue charring, these light microscopic findings were not observed. Likewise, scanning microscopy consistently confirmed the histologic findings associated with gross charring and, in the absence of charring, disclosed only wrinkling or pruning of the myocytes bordering the laser crater. The extent of ultrastructural alteration of myocytes adjacent to the laser crater was, in the worst case, limited to less than 650 μ in each specimen irradiated with a pulsed laser at low repetition rates. Both this finding, as well as the presence or absence of the light microscopic correlate (linear discoloration), could not be correlated with a single specific variable of the pulsed energy profile.

Discussion

Pathologic examination of cardiovascular tissues irradiated with CW lasers has consistently disclosed gross charring at the perimeter of the laser crater, and distinctive light microscopic findings: a superficial, linear zone of coagulation necrosis, and a subjacent zone of polymorphous lacunae.[1–9] Furthermore, the photoproducts generated by CW laser irradiation of cardiovascular tissues have been shown to be those typical of a thermal process.[10] Thus, these gross and histologic findings have been interpreted as the result of thermal injury. The results of the present investigation suggest that gross and light microscopic signs of injury associated with CW laser tissue ablation can be eliminated by pulsed energy delivery using high peak powers and low repetition rates.

CW lasers used in an "intermittent" or "chopped" mode must be differentiated from a true pulsed laser. The CW laser may be used in 2 ways: continuous or

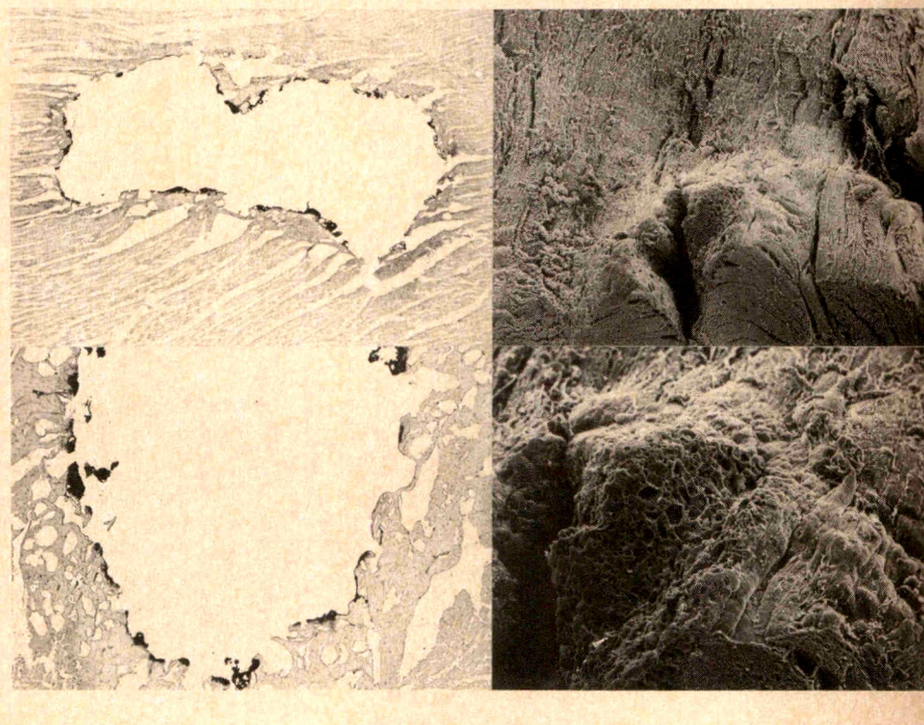

FIGURE 2. Light microscopic and ultrastructrual findings after pulsed laser irradiation with high repetition rate. **Upper** and **lower left,** light microscopic findings of coagulation necrosis and polymorphous lacunae resulted from mode-locked argon laser (515 nm, 256 MHz, 65-second exposure, average power = 0.7 W) (**upper left**) and pulsed Nd-Yag (1,064 nm, 10 KHz, 29 seconds, 10.5 W). (**Upper** and **lower right**): scanning electron photomicrographs of thermal injury resulting from mode-locked argon laser (515 nm, 256 MHz, 33 seconds, 1.0 W) **upper left,** H-E × 10; **lower left,** H-E × 25; **upper right,** × 31.6; **lower right,** × 100—reduced by 50%.

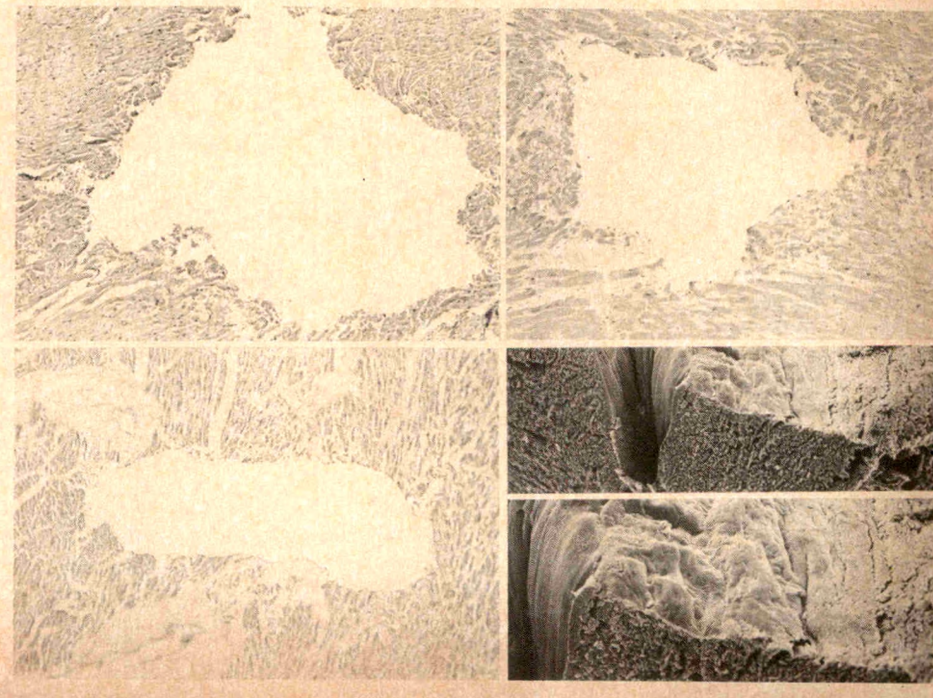

FIGURE 3. Light microscopic and ultrastructural findings after pulsed laser irradiation with low repetition rate. Neither of the typical light microscopic signs of thermal injury (coagulation necrosis and polymorphous lacunae) are observed after pulsed laser irradiation with (**upper left**) Nd-YAG-532 (10 Hz, 3-second exposure, 350 mJ); (**upper right**) Nd-YAG (1,064 nm [10 Hz, 7 seconds, 190 mJ]); and (**lower left**) excimer (248 nm [10 Hz, 5 seconds, 250 mJ]). Scanning electron photomicrograph at **lower right** shows lower power (× 62.1) and higher power (× 101) views of myocardial trough after excimer laser (200 Hz, 41 seconds, 3 mJ) irradiation. The walls of the trough are smooth with only rare lacunae. The surface at the perimeter of the trough has a wrinkled pruned appearance. **Upper left,** H-E × 25; **upper right,** H-E × 25; **lower left,** H-E × 4, reduced by 50%.

periodically interrupted. The latter has been referred to as an intermittent or chopped mode. Intermittent or chopped differs from continuous delivery only with respect to emission-free intervals; power output during intervals of laser emission is identical for both modes. This is in marked contrast to true pulsed lasers. In common with the chopped mode, pulsed lasers include emission-free intervals. Unlike chopped lasers, however, pulsed lasers use a variety of techniques (e.g., mode-locking or Q-switching) that allow energy storage within the laser cavity; as a result, each emission is characterized by a peak power substantially greater than the continuous power output of a CW laser.

The distinction between chopped and pulsed, as well as considerations regarding pulse duration and repetition rate, are directly relevant to the reduction in laser-induced tissue injury demonstrated in this study. Experiments by Hayes and Wolbarsht,[12] Welch,[16] and Anderson and Parrish[17] have suggested that thermal injury of adjacent, nontarget tissues can be avoided when exposure time used for each pulse is shorter than the thermal relaxation time (characteristic time for first-order temperature dissipation) of the irradiated tissue. If the pulse duration and cumulative exposure are sufficiently brief, and if the interval between each pulse is sufficiently long, then the heat generated by each pulse may be sufficiently dissipated before delivery of the subsequent pulse. Consequently, thermal injury of tissue outside the path of the laser beam can be avoided.

Although pulsed delivery at low repetition rates in an air-tissue interface clearly eliminates gross microscopic evidence of thermal injury, studies demonstrating that these findings can be reproduced in a blood-filled system are needed. Furthermore, the present series of experiments does not establish that this superior histologic appearance is a result of enhanced dissipation of heat during the thermal process or a nonthermal (photochemical[18] or photodisruptive[19] process. To achieve a given volume of tissue ablation, if the number of pulses and the duration of each pulse are reduced, then sufficient power (watts) can be achieved only by increasing pulse energy. As a result, pulsed lasers with low repetition rates and brief pulse durations are characterized by high peak powers (pulse energy/pulse duration). Consequently, the effects of improved thermal relaxation (accomplished at reduced repetition rate and pulse duration) are difficult to separate from those of high peak power. In the present series of experiments, for example, peak powers unassociated with pathologic tissue injury were consistently in the megawatt range. The photon density resulting from such peak powers may possibly ablate tissues by a nonthermal process.

Athough the absence of charring was observed only with energy profiles that necessitated the use of a focusing lens, this smaller spot size and resultant higher photon density alone did not account for the absence of pathologic injury. Both the CW argon laser and the rapidly pulsed (more than 2 kHz) Nd-YAG laser resulted in pathologic injury when used with a focusing lens.

The choice of myocardial slices for these experiments was based on the requirement for homogeneous tissue with uniform slice thickness that would allow meaningful comparison among various laser wavelengths and energy profiles. The optimal combination of energy profile and wavelength for atherosclerotic segments of coronary arteries may vary from those used to irradiate myocardium. Nevertheless, our experience with excimer laser irradiation[20] suggests that the reduction in pathologic injury of myocardium accomplished by pulsed energy delivery is transferrable to atherosclerotic plaque.

Elimination of pathologic alterations such as coagulation necrosis and polymorphous lacunae in residual laser-irradiated tissue is potentially advantageous. A more benign healing process, a less thrombogenic surface, and improved preservation of structural tissue integrity may be reasonably anticipated. However, these remain only potential advantages; no long-term, in vivo data are available. Furthermore, chronic (albeit relatively short-term and relatively limited) studies involving CW laser irradiation[21,22] have failed to establish clearly deleterious consequences of thermal injury associated with CW laser irradiation.

Finally, because the high peak powers characteristic of the energy profiles used here to avoid pathologic tissue injury cannot be coupled to commercially available fiberoptics, clinical application of these energy profiles must be limited to direct surface (e.g., intraoperative) irradiation. Even with this restriction, however, such energy profiles may be used to advantage, e.g., to perform intraoperative ablation of pathologically thickened endocardium.[8] The absence of any tissue charring in such a procedure would facilitate recognition of underlying myocardium after ablation of the overlying endocardial scar. Percutaneous application of these pulsed profiles, however, will require development of fiberoptics and coupling mechanisms capable of transmitting such high peak powers.

Effects of Hematoporphyrin Derivative and Photodynamic Therapy on Atherosclerotic Rabbits

FRANK LITVACK, MD, CM, WARREN S. GRUNDFEST, MD, JAMES S. FORRESTER, MD, MICHAEL C. FISHBEIN, MD, H.J.C. SWAN, MD, PhD, ELIOT CORDAY, MD, DAVID M. RIDER, PhD, I. STUART McDERMID, PhD, THOMAS J. PACALA, PhD, and JAMES B. LAUDENSLAGER, PhD

This study was performed to demonstrate selective uptake of hematoporphyrin derivative (HPD) within actively developing atheroma, to localize the site of uptake of HPD within the atheroma, and to determine the potential for photodynamic therapy (PDT) of atherosclerosis in the rabbit model. Fifteen rabbits were rendered atherosclerotic. Five rabbits received neither HPD nor PDT and 2 rabbits received HPD, 10 mg/kg intravenously, without subsequent irradiation. Eight other rabbits received 5 to 20 mg of HPD intravenously and subsequent intravascular 636-nm laser radiation to either the thoracic aorta or the aortic arch. A total of 32 to 288 J of laser energy was delivered through a 300-μ quartz fiber. All rabbits that received in vivo HPD had red fluorescence of their aortas when placed under ultraviolet light. The pattern of fluorescence corresponded precisely to the pattern of atheroma. In segments that received PDT, light microscopic examination revealed an accumulation of smooth muscle cells at the intimal surface. Fluorescence microscopy revealed a diminishing concentration gradient of HPD from intimal surface layers towards the media. Assessment of treated thoracic aortic segments revealed quantitative and qualitative differences compared with control segments. In the arch-treated segments, however, no changes were seen. It is concluded that HPD localizes within rabbit atheroma, can be detected by fluorescence and is deposited in a diminishing concentration gradient from lumen toward media. Irradiation with 636-nm light may induce qualitative and quantitative changes in atheroma.

Naturally occurring porphyrins accumulate in rapidly proliferating cells.[1] Hematoporphyrin derivative (HPD), made from natural hematoporphyrin,[2] has been used for the diagnosis and treatment of neoplastic disorders.[3–7] HPD possesses 2 characteristics that make it useful for these purposes. First, when irradiated with ultraviolet light, HPD fluoresces, allowing for detection of HPD containing cells.[3,4,8] Second, when irradiated with light of a variety of wavelengths, HPD photoactivates and becomes cytotoxic.[5,9,10] Singlet oxygen gen-

eration has been identified as the likely mechanism for HPD-induced destruction of murine tumor.[11] Although HPD has absorption maxima at short wavelengths, most experience with photodynamic therapy (PDT) of neoplasms has been with light at or about 635 nm.[12] Recently, HPD was shown to be taken up in plaque but not in normal aortic segments of 4 atherosclerotic rabbits and 1 monkey.[13] The purposes of this study were to confirm selective uptake of HPD within atheroma, to localize the site of uptake of HPD within the atheroma, to demonstrate the potential for PDT of atherosclerosis in the rabbit model.

Methods

Fifteen white male New Zealand rabbits were fed a diet of Purina Rabbit Chow (Ralston Purina Co.) supplemented with 3% by weight of cholesterol (Sigma Co.) dissolved in peanut oil. Feedings continued from 12 to 16 weeks. Five rabbits re-

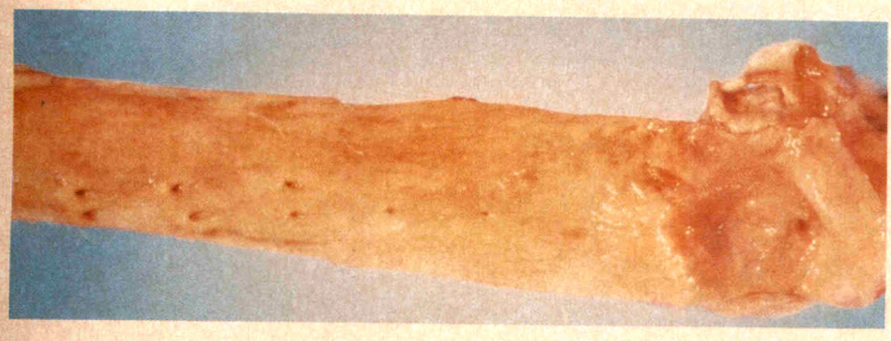

FIGURE 1. Aorta from a control rabbit. The atheroma involvement was graded as smooth and extensive.

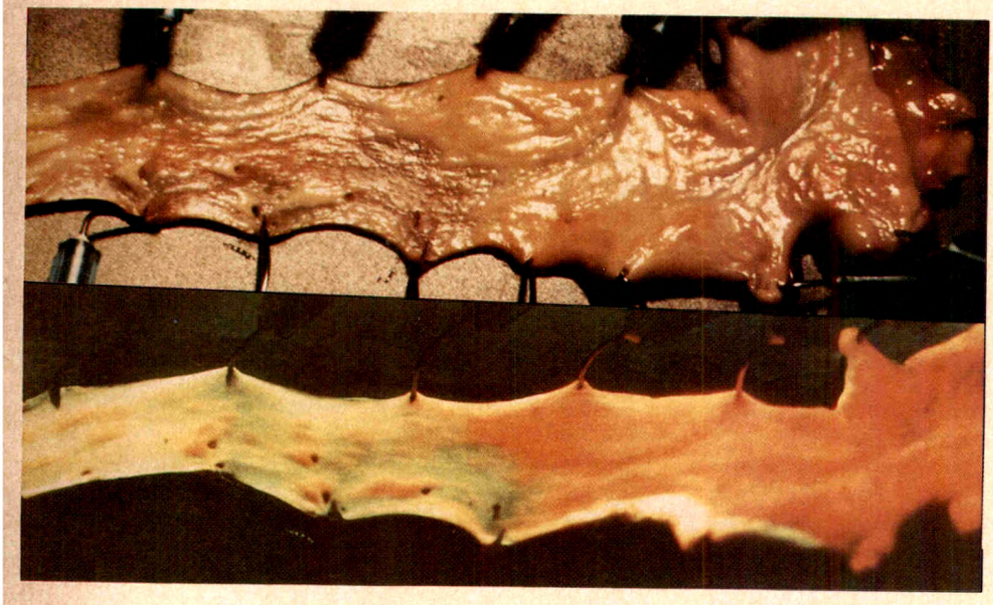

FIGURE 2. A, aorta of a rabbit that received 32 J in the thoracic aorta. The atheroma was classified as minimal and fissured. **B,** the same aorta under a Woods lamp. The atheroma fluoresces orange and the intensity is greatest in the arch and diminishes distally.

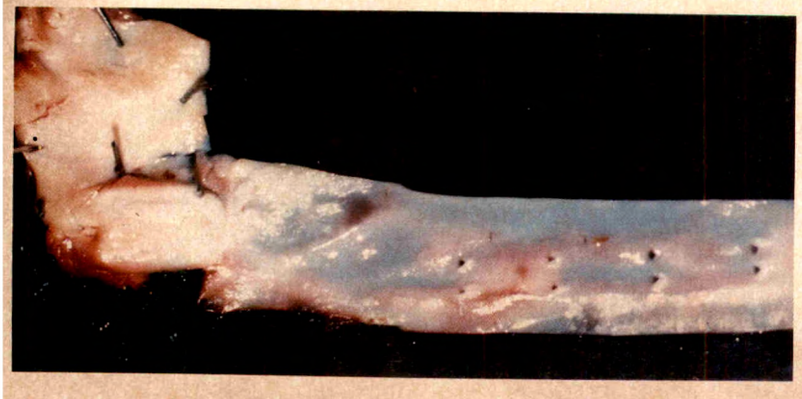

FIGURE 3. Aorta from a rabbit that received 10 mg/kg of hematoporphyrin derivative and 89 J to the thoracic aorta. At 14 days the irradiated zone is atheroma free and glistening.

FIGURE 4. Aorta from a rabbit that received 20 mg/kg of hematoporphyrin derivative and 288 J to the aortic arch. At 14 days the atheroma in the irradiated zone is smooth and extensive.

ceived neither HPD nor PDT. Two rabbits received 10 mg/kg of HPD but no irradiation. These 2 rabbits were killed at 48 and 72 hours after injection. Eight additional rabbits received from 5 to 20 mg/kg of HPD and PDT. These rabbits were killed at 3 hours, 1 week or 2 weeks.

HPD (Photophrin Medical Inc.) was obtained in a concentration of 5 mg/ml. In the 10 rabbits that received HPD, it was injected into an ear vein and then maintained in their regular environment and lighting conditions.

The 636-nm red light used for HPD photoactivation originated from a tunable organic dye laser (Lambda Physik 2000E) filled with a Rhodamine B dye and pumped by a pulsed excimer laser (Lambda Physik 101E). Light was carried from the laser output by 300-μ-core flexible quartz fiberoptic waveguide with an exit divergence angle of 30 to 45°. Pulse duration was 10 ns with a frequency of 40 Hz. Fibertip power output was measured both before insertion of the fiber and at the termination of the irradiation sequence by a laser precision RK 3230 powermeter. Based on measurements obtained at termination of the procedure, the average powers ranged from 12 to 33 mW and yielded peak powers of up to 100 kW. Minimum total energy delivered to the rabbit aortas ranged from 32 to 288 J.

The waveguide was introduced through either the carotid or femoral artery and placed in either the descending thoracic aorta or the arch. Catheter position was determined by transillumination of the chest wall. The dose of HPD, the time to sacrifice after treatment, the site of irradiation and the total energy delivered is shown in Table I. During the period between treatment and sacrifice, the rabbits were fed a regular (nonsupplemented) diet. At necropsy, the aorta was dissected from aortic valves to below the bifurcation, washed with saline solution, opened longitudinally and pinned. It was inspected grossly and photographed with an Olympus OM-1 camera. Each atheroma was classified as either fissured or smooth. The

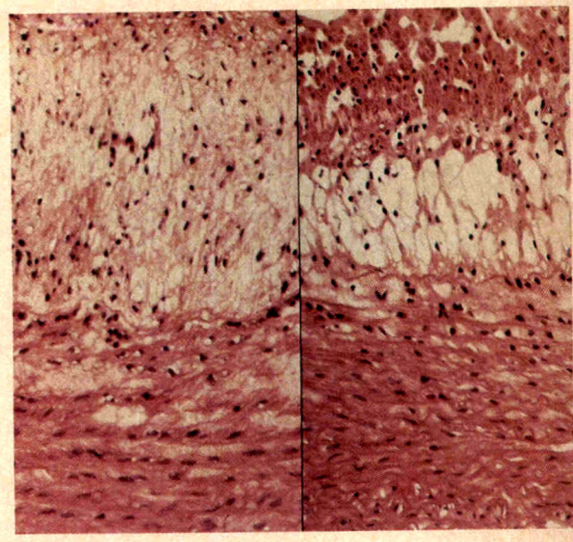

FIGURE 5. A, segment of abdominal aorta. The atheroma has the typical appearance seen in this rabbit model. **B,** segment from the irradiated zone within the aortic arch. Smooth muscle cells have accumulated at the surface of the intima.

area of intimal involvement was graded as absent, minimal, moderate or extensive. The specimen was then placed under ultraviolet light from a Woods lamp and rephotographed through a Tiffen yellow (minus blue) filter. In addition to the vascular tissues, the gastrointestinal mucosa was also examined under the Woods lamp at necropsy. Specimens of aortic tissue from both irradiated and nonirradiated zones and specimens of lung, liver and kidney were submitted for standard and fluorescence microscopy.

Results

Figure 1 shows the aorta of a control rabbit. The intima is diffusely involved with white atheroma. The atheroma involvement was graded as smooth and extensive.

Figure 2A shows the aorta of a rabbit that received 10 mg/kg of HPD and at 72 hours at least 32 J of laser irradiation with the fibertip positioned just below the arch. The intima was classified as minimal and fissured. The atheroma appears as islands with discrete depressed linear tracks of either normal or near normal intima. Furthermore, the atheroma appears yellow. In no nonirradiated segments did the pattern of atheromatous involvement take on this fissured appearance with yellowing of the plaque.

Figure 2B shows the same aorta under a Woods lamp. The grossly atheromatous area fluoresces orange under ultraviolet light. The intensity of fluorescence is greatest in the arch and diminishes distally. The fissured plaque fluorescences and the areas of greatest fluorescent intensity correspond to thicker plaque. In all rabbits that received HPD, regions of fluorescence corresponded precisely to the presence of gross atheroma. No untreated rabbits exhibited fluorescent atheroma under Woods irradiation.

Figure 3 shows our most striking result. This aorta is from a rabbit that received 10 mg/kg of HPD and at least 89 J of laser irradiation to the thoracic aorta. The rabbit was killed 14 days after irradiation. The proximal portion of the aorta is covered by dense white atheroma. The thoracic aorta is virtually free of atheroma and the intima has a glistening appearance. Even at the origin of the lumbar arteries, a site where we uniformly see atheroma deposition in this model, no atheroma is seen. At the junction zone between the thoracic aorta and the arch, there appears to be small, discrete, broken-up islands of atheroma. Under Woods irradiation the arch of the aorta, which was grossly atheromatous, did fluoresce faintly. No fluorescence was seen over the thoracic aorta.

Figure 4 shows our least striking result. This aorta was taken from a rabbit that received 20 mg/kg of HPD and at least 288 J of laser irradiation in the aortic arch. The area of irradiation over the aortic arch was classified as smooth and extensive.

Figure 5A shows an abnormal aortic segment from the previous rabbit, taken far from the location of the fibertip. The atheroma has the typical appearance seen in this rabbit model. The intima is thickened and diffusely infiltrated by smooth muscle cells. Figure 5B is taken from the aortic arch, which was directly within the zone of irradiation. There is a dense accumulation of smooth muscle cells just at the surface of the intima as opposed to the diffuse infiltration seen in the control segment. This particular histologic characteristic was seen more often, although not exclusively, in irradiated segments.

Figure 6 is a fluorescent photomicrograph of the aortic arch of the same rabbit as is shown in Figure 5. The intima fluoresces orange and the intensity of fluorescence gradually diminishes from the luminal surface toward the media, implying a diminishing HPD concentration gradient. Under higher power examination, the fluorescence was located within the intercellular matrix and the cellular matter of the intima. The green fluorescence is a fluorescence of elastin fibers routinely encountered in this preparation.

In the rabbits that received PDT, no histologic injury was seen in the lungs or liver. Fluorescence microscopy in rabbit 15 revealed some fluorescence within the renal tubules. No cholesterol emboli were seen on histologic examination of any organs.

Table I is a summary of our results. Rabbits 1 through 7 were controls. The area of aortic involvement was always graded as either moderate or extensive, and the atheroma was always graded as smooth. Rabbits 8 through 11 received 10 mg/kg of HPD and thoracic aorta irradiation. Rabbit 8 hemorrhaged and died 3 hours after irradiation. The aortic atheroma was graded as smooth and extensive, indicating no acute laser effect. Rabbits 9 and 10 were killed at 7 days. The atherosclerosis was classified as moderate and minimal, respectively, and both were graded as fissured. Rabbit 11 was killed at 14 days and was our most striking example. Rabbits 12 to 15 received irradiation in the aortic arch. Atherosclerosis in all 3 was classified as smooth and extensive.

Discussion

Our findings demonstrate that HPD, when administered intravenously in rabbits maintained on an atherogenic diet, localizes selectively within atheroma. Atheroma not treated with HPD do not fluoresce under ultraviolet light. The precise topographic correlation between visible atheroma and fluorescence pattern in this study confirms and substantiates the findings of Spears et al,[13] who found fluorescence, but confined their observations to 48 hours after HPD injection. Our study confirms bright fluorescence at 72 hours and shows that fluorescence persists at 1 week, with faint fluorescence at 14 days.

Our findings show that the concentration of HPD is greatest at the intimal surface layers and diminishes toward the media. Although the mechanism of HPD concentration within atheroma is not established, one may speculate based on current knowledge. The smooth muscle cell is recognized as the proliferative cell in atherogenesis.[14–16] In a manner analogous to its uptake in rapidly proliferating tumor cells, HPD could be selectively concentrated within the proliferating smooth muscle cells of atheroma. However, the mucosa of the gastrointestinal tract of our rabbits did not exhibit fluorescence. The mucosal cells of the intestine are among the most rapidly proliferating in the body; therefore, it is unlikely that HPD uptake is related only to the rate of cell proliferation.[17] Localized increase in endothelial cell permeability to lipid is also pivotal in

TABLE I Methods and Results for the 15 Rabbits

HPD = hematoporphyrin derivative.

atherogenesis.[18] Because HPD is lipophilic, it may have moved selectively into atheroma along with lipoprotein molecules. This hypothesis is supported by our finding of diminishing concentration gradient of HPD from luminal surface inward.

A fundamental and insurmountable limitation of our study design was that the delivery of laser energy in a flowing blood stream precluded both precise localization of the impact site and quantitation of the amount of energy delivered to any site on the arterial wall. For this reason we view our results as equivocal as to the potential for PDT. The apparent atherolysis in the thoracic aorta may actually be a reflection of biologic variation in severity of atherosclerosis. Conversely, the apparent lack of effect during aortic arch irradiation may be a result of insufficient sensitivity of our gross anatomic and histologic methods. For example, a 50% reduction in thickness of the plaque of the arch could not have been readily perceived. Our histologic analyses demonstrated differences between irradiated and untreated segments, but these findings were not sufficiently dramatic to be considered unequivocal.

Our mode of laser delivery differed from carcinoma therapy,[6,7] in which the continuous mode is commonly used. In our system the laser was pulsed. The high peak powers achieved with nanosecond pulsing may provide more efficient photoactivation than continuous-mode activation by inducing nonlinear multiphoton processes for HPD activation.[19]

The findings of our study may have several implications. Recent advances in fiberoptic technology have allowed construction of ultrathin flexible endoscopes. Clear images of intravascular structures can be obtained in living animals and in humans.[20] By means of intervascular ultraviolet illumination and HPD, it may be possible to localize atheroma with great precision. Furthermore, serial angioscopic examination may provide a means for sequential observation of a segment after PDT.

We have shown that HPD localizes within rabbit atheroma. The pattern of localization is a continuously diminishing concentration gradient from the endothelial surface toward the media. The HPD is heavily concentrated at 2 days, and persists in diminishing intensity until about 2 weeks. Laser energy delivered through a small-diameter catheter (300 μ) in a flowing blood stream appears to induce gross and histologic changes in some rabbits, although the findings are not consistent.

Effect of Intracoronary Verapamil on Infarct Size in the Ischemic, Reperfused Canine Heart: Critical Importance of the Timing of Treatment

HUEY-MING LO, MD, ROBERT A. KLONER, MD, PhD, and EUGENE BRAUNWALD, MD

In an effort to determine whether the beneficial effect of calcium blocking drugs occurs only during ischemia or during reperfusion as well, anesthetized dogs were subjected to 3 hours of occlusion of the left anterior descending coronary artery followed by 3 hours of reperfusion. In protocol A, intracoronary verapamil (0.01 mg/kg/min) was begun 90 minutes after coronary occlusion and continued for 1 hour into the reperfusion phase (n = 6) while a control group received an infusion of saline solution (n = 6). In vivo area at risk determined by dye injection was 29 ± 3% of the left ventricle (± standard error of the mean) in the control group and 30 ± 3% in the verapamil group (difference not significant [NS]), whereas the area of necrosis determined by triphenyltetrazolium staining and expressed as a percent of area at risk was smaller in the verapamil group (29 ± 8%) than in the control group (57 ± 8%, $p < 0.05$). In protocol B, verapamil infusion into the left anterior descending coronary was begun 5 minutes before blood reperfusion and continued throughout the 3-hour reperfusion phase. Area at risk was similar in both groups (control, 25 ± 1%, n = 8; verapamil, 28 ± 2%, n = 8 , NS); area of necrosis expressed as a percentage of area at risk was 49 ± 6% in the control group and 45 ± 10% in the verapamil group (NS). Therefore, calcium blockade of ischemic myocytes delays death and enhances salvage produced by reperfusion. However, calcium blockade begun after prolonged coronary occlusion does not enhance reperfusion-induced myocardial salvage.

(Am J Cardiol 1985;56:672–677)

Considerable interest has recently focused on the development of techniques for reperfusion of the ischemic myocardium in an effort to limit infarct size.[1–6] Reperfusion must be carried out within a few hours in order to salvage a significant quantity of myocardium.[7] In the clinical realm there is a lag time between the onset of coronary occlusion and successful thrombolysis. It would be useful if the degree of cell death that occurs during this period could be reduced or delayed before reperfusion.

Experimental studies have also raised the question of whether reperfusion exerts a deleterious effect—so-called reperfusion injury.[8] Upon reperfusion after a period of myocardial ischemia, ischemic myocytes gain large quantities of Ca^{++}, as reflected in flux studies, using radioactive Ca^{++} [9,10] and as evidenced by the appearance of intramitochondrial dense bodies containing large quantities of Ca^{++} and by the development of myocardial contracture.[9–12] It has been proposed that the entry of excess Ca^{++} during reperfusion leads to inhibition of mitochondrial energy production, which leads to cell death.[9,13,14] Voltage-dependent calcium channels which can be blocked by calcium entry antagonists are one of the potential routes by which myocytes gain calcium during reperfusion.

There has been considerable interest in the use of calcium channel blocking in protecting ischemic myocardium.[15–17] Some of this interest stems from the concepts of calcium overload that occurs upon reperfusion as discussed herein. The purpose of this study was to determine whether the administration of a calcium blocking drug significantly *after* coronary occlusion enhances reperfusion-induced myocardial salvage. We report the effects of verapamil when administered during the period of induced ischemia and during the first hour of reperfusion, and when administered only during the 3-hour period of reperfusion.

Methods

Mongrel dogs of either sex that weighed 17 to 34 kg were anesthetized with sodium pentobarbital, 30 mg/kg intravenously. The dogs were intubated and ventilated with a Harvard respirator (model 607) at approximately 300 ml of room air/kg body weight/min. The chest was opened in the fifth intercostal space; the pericardium was opened and the heart suspended in a pericardial cradle. A fluid-filled catheter was placed in the left common carotid artery and connected to a Statham P23Db transducer to monitor arterial pressure and heart rate. Catheters were also placed in the left external

jugular vein for intravenous infusion and in the left atrium for injection of radioactive microspheres for measurement of regional blood flow. A long segment of the left anterior descending coronary artery (LAD) was dissected free just distal to the first diagonal branch. After baseline hemodynamic data were recorded, lidocaine, 1.5 mg/kg, was given as an intravenous bolus injection. The LAD was then occluded with an atraumatic Schwartz clamp. Fifteen minutes after occlusion, an injection of radioactive microspheres (8 to 10 μm) was made into the left atrium for measurement of regional myocardial blood flow. The dogs were subjected to 3 hours of coronary occlusion and 3 hours of reperfusion induced by releasing the clamp, and were randomized into a verapamil-treated or a control group at 1 hour after occlusion as follows (Fig. 1).

In protocol A, an intracoronary infusion of verapamil, 0.01 mg/kg/min, into the LAD was begun 90 minutes after occlusion, while the occlusion was maintained for an additional 90 minutes. Verapamil infusion was continued for the first of the 3 hours of reperfusion; a control group of dogs received intracoronary infusion of saline solution. In protocol B, the same dose of intracoronary verapamil infusion (0.01 mg/kg/min) was infused commencing 5 minutes before the onset of reperfusion, i.e., after 175 minutes of occlusion, and was continued throughout the 3-hour reperfusion period. A control group received intracoronary saline solution.

The LAD was cannulated with a 22 gauge intravascular catheter for intracoronary administration of verapamil or saline solution. Cannulation was carried out just before commencing intracoronary infusion and a Harvard pump (model 940) was used for constant intracoronary infusion.

When the experiment was completed, an in vivo area at risk was determined by injecting Monastral blue, 1 ml/kg, into the left atrium with the LAD reoccluded; the heart was then excised. The left ventricle was cut free and then sliced in sections 0.5 cm thick. A clear acetate overlay was placed over the heart slices, and the perfusion defect (myocardium not stained blue, i.e., the area at risk) and the perfused area (myocardium that was stained blue, i.e., the area not at risk) were traced. The heart slices were photographed and then incubated with triphenyltetrazolium chloride to detemine the area of necrosis. Area of necrosis similarly was traced onto an acetate overlay and the heart slices were then photographed. Area at risk and area of necrosis were determined by planimetry using these tracings and corrected for weight of the left ventricular slices. Area at risk was expressed as a percentage of the left ventricle and area of necrosis was expressed as a percentage of area at risk. Hemodynamic data, including heart rate, systolic blood pressure and diastolic blood pressure, were obtained just before occlusion, before drug administration, 1 hour after blood reperfusion, and 3 hours after reperfusion. The investigators were blinded to the results during the study period; specifically, the investigators who determined the area of necrosis and area at risk were not aware of which dogs were treated or which were controls.

Statistical analysis: For paired comparisons, a Student *t* test was used. Hemodynamic data were analyzed by a repeated-measures analysis of variance. Differences were considered significant at the $p < 0.05$ level. Values are expressed as mean ± standard error of the mean.

Results

Fifty-two dogs were entered into the study. Twenty-four dogs were excluded: 16 because of ventricular fibrillation, 3 because of absence of detectable epicardial cyanosis within the first 2 minutes of occlusion, 3 because of poor resolution of the area at risk and 2 because of failure of LAD cannulation. After these exclusions, 12 dogs remained in protocol A and 16 in protocol B.

Area at risk (Table I): Because area of necrosis is a function of area at risk, the area at risk must be compared for each group. In this study, the area at risk was similar between control and verapamil-treated groups in both protocols. In protocol A, area at risk was 29 ± 3% for the control group (n = 6) and 30 ± 3% for the verapamil group (n = 6), NS. In protocol B, area at risk was 25 ± 1% for the control group (n = 8) and 28 ± 2% for the verapamil group (n = 8) (difference not significant [NS]).

Regional myocardial blood flow (RMBF) (Table II): In addition to the gross observation on the development of epicardial cyanosis and contractile abnormality after LAD occlusion, RMBF was assessed 15 minutes after occlusion to assure a comparable ischemic insult in control and treated dogs. In protocol A, the subepicardial blood flow to the ischemic area was 0.17 ± 0.09 for the control group and 0.21 ± 0.10 for the verapamil group, (NS); the subendocardial blood flow in the ischemic zone was 0.05 ± 0.02 for the control

* $p < 0.05$ vs control protocol A.
† $p < 0.05$ vs pretreatment.
C = control; DBP = diastolic blood pressure; DP = double product; HR = heart rate; SBP = systolic blood pressure; V = verapamil.

group and 0.08 ± 0.06 for the verapamil group (NS). Similarly, in protocol B, the subepicardial blood flow in the ischemic zone was similar for both groups (0.37 ± 0.11 in control group and 0.25 ± 0.11 in verapamil group, NS), and the same was true for the ischemic subendocardial blood flow (0.04 ± 0.01 in control group and 0.05 ± 0.02 in verapamil group, NS).

Hemodynamics (Table III): There were no significant differences in heart rate or blood pressure between treatment groups, prior to verapamil therapy. In protocol A, the diastolic arterial pressure and double product in the verapamil group were significantly lower after verapamil than in the control group 1 hour and 3 hours after reperfusion. In protocol B, diastolic blood pressure was decreased in the verapamil group, but the differences between the treated and control groups were not statistically significant.

Area of necrosis/area at risk (Table I, Fig. 2): In protocol A, in which verapamil administration was begun 90 minutes after coronary occlusion, the area of necrosis, expressed as percentage of area at risk, was significantly smaller in the verapamil group (29 ± 8%) than in the control group (57 ± 8%, $p < 0.05$) (Fig. 3 and 4). In contrast, in dogs in which verapamil administration was begun after 3 hours of coronary occlusion, area of necrosis expressed as a percentage of area at risk was not altered by treatment (45 ± 10% for verapamil group and 49 ± 6% for control group, NS).

Discussion

With the widespread use of thrombolytic therapy in the treatment of acute myocardial infarction, it is of interest to determine whether the intracoronary administration of a calcium channel blocker at the time of reperfusion can enhance the myocardial salvage caused by reperfusion. Our results indicate that in the dog, intracoronary verapamil begun after 3 hours of LAD occlusion and at the time of coronary reperfusion did *not* provide additional myocardial salvage. However, intracoronary verapamil begun during the ischemic period, even in a delayed fashion, i.e., 90 minutes after occlusion, enhanced substantially the myocardial salvage achieved by reperfusion. These results suggest that the intervention of calcium blockade at the time of reperfusion does not salvage ischemic myocardium. The results support the concept that at the end of the period of ischemia, all myocardial cells that are destined to die are already irreversibly injured and that reperfusion per se does not increase the number of cells which die. Nevertheless, we cannot rule out the possibility that other agents may be beneficial when administered during the reperfusion phase.

Although the mechanism of the observed myocardial salvage is not known, it is postulated that a substantial population of mildly, reversibly injured subepicardial myocytes is present at 90 minutes after occlusion compared with that at 3 hours. Most of the calcium channels of these myocardial cells are presumably still functioning and can still be blocked by verapamil. In a study using voltage clamp techniques, diltiazem exerted a more profound calcium channel blocking action on ventricular myocardium at a potential of −61 mV than of −120 mV.[18] Thus, calcium antagonists may exert a greater blocking effect on ischemic than normal myocytes because the former have a decreased resting membrane potential.[19] This would exert an antiischemic

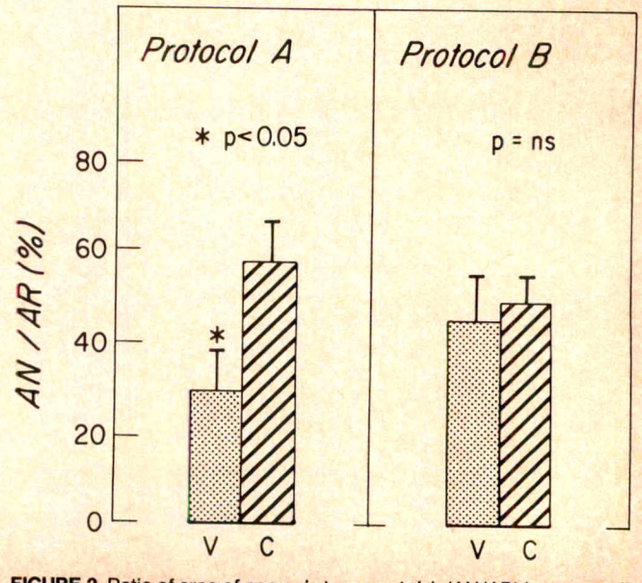

FIGURE 2. Ratio of area of necrosis to area at risk (AN/AR) in verapamil (V) groups (**stippled bars**) and control (C) groups (**striped bars**) of protocols A and B.

action and minimize energy expenditure of cells that were only reversibly injured. In accord with this hypothesis, Smith et al[20] showed that verapamil exerts a selective depression of function of the ischemic myocardium, and thereby presumably exerts a more potent protective effect in these cells. Serruys et al[21] reported that regional administration of nifedipine had a direct negative inotropic effect on the myocardium suggesting it might spare regional O_2 consumption. Furthermore, decreased calcium influx into ischemic myocardium preserves both mitochondrial function and ultrastructure with subsequent preservation of myocardial ATP.[22–26] Nayler et al[27] showed that when verapamil was added to the perfusate at the very start of hypoxic perfusion of isolated guinea pig hearts, it attenuated the hypoxia-induced increase in resting tension (contracture). However, when this calcium antagonist was added only *after* the start of hypoxia, when resting tension already had begun to increase, it failed to diminish this increase in resting tension. Similarly, Klein et al[17] showed that in the pig heart rendered ischemic for 75 minutes and then reperfused for 4 hours, pretreatment with diltiazem reduced infarct size beyond the reduction achieved by reperfusion, whereas diltiazem begun during ischemia had a smaller and statistically insignificant effect.[17]

The mechanism of the salutary action of verapamil may also have been related to its systemic hemodynamic action as well as to its effect on calcium entry into ischemic myocytes. Thus, in protocol A, the verapamil-treated dogs had significantly lower diastolic pressures and systolic pressure–heart rate products, both after 1 and 3 hours of perfusion, than control dogs. These factors may have contributed to a lowering of myocardial oxygen demand during ischemia.

When verapamil was infused after 3 hours of ischemia, no enhancement of myocardial salvage occurred. Presumably, at this time it did not have the opportunity to exert an antiischemic effect on myocytes, which were already irreversibly damaged and which became necrotic despite reperfusion.

The dosage of verapamil we chose for intracoronary administration is comparable to that used systemically in patients. The purpose of intracoronary administration was to maximize the potential for myocardial salvage. In our pilot studies, this dosage and route of administration were well tolerated, but it is close to maximal, since 2:1 atrioventricular block developed when the dose was doubled.

The action of calcium channel blockers in enhancing reperfusion-induced myocardial salvage is probably not unique. Indeed, we have observed that timolol,[28] a β-adrenergic blocking drug, and esmolol,[29] an ultrashort-acting β-blocking drug, when given soon after coronary occlusion, can substantially augment reperfused-induced salvage of ischemic myocardium.

In the present study, infarct size was assessed by the triphenyltetrazolium chloride technique. This tech-

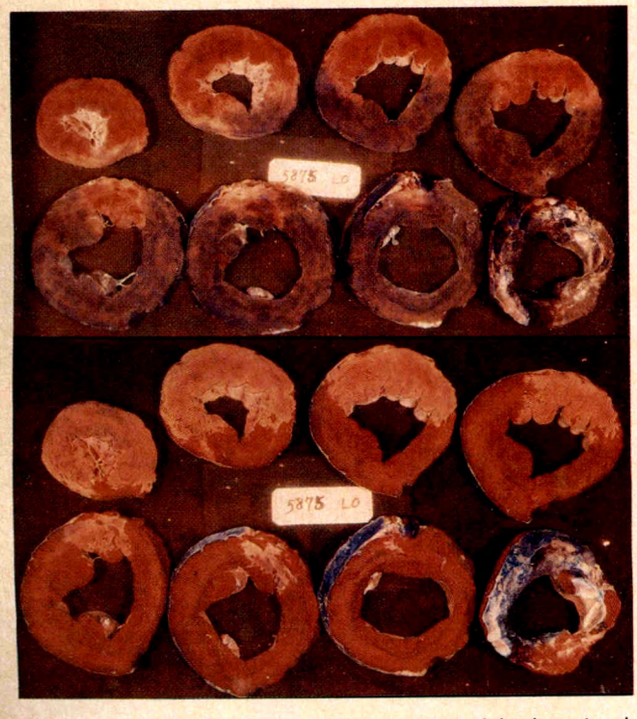

FIGURE 3. Top, left ventricular slices from a control dog in protocol A showing the nonischemic area (blue) and unstained pink area at risk. **Bottom,** left ventricular slices from the same dog as in panel A after incubation in triphenyltertazolium chloride. The infarct appears as the pale tissue and corresponds closely to the area at risk.

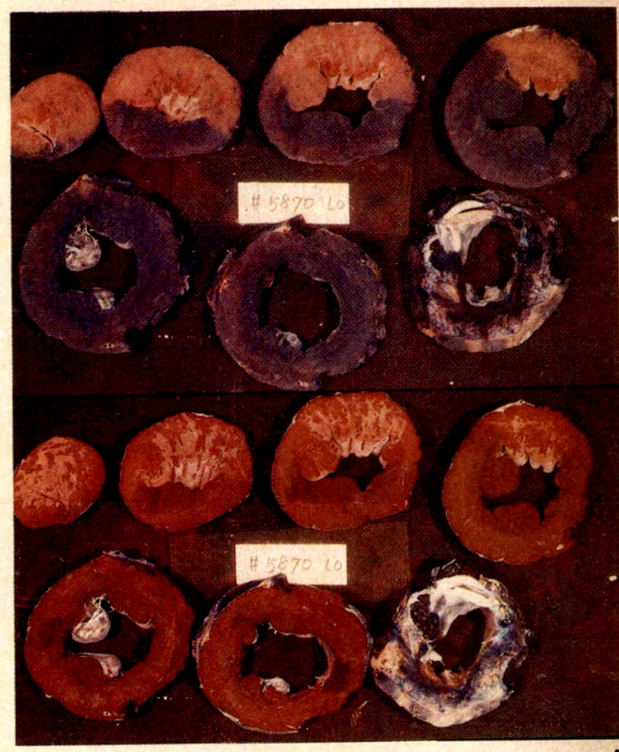

FIGURE 4. Top, left ventricular slices from a verapamil-treated dog in protocol A showing the nonischemic area (blue) and unstained **pink** area at risk. **Bottom,** left ventricular slice from the same dog as in panel A after incubation in triphenyltetrazolium chloride. The infarct appears as the pale tissue and is much smaller than the area at risk and smaller than the infarct shown in Figure 3B. While most salvage occurs in the subepicardium, there are areas where salvage (noninfarcted tissue within the risk zone) appears along the lateral edge of the infarct. This is most apparent in the third ventricular slice from the apex.

nique reliably localizes and sizes infarcts early after myocardial ischemia.[30–34] In our laboratory, infarcts assessed by triphenyltetrazolium chloride have shown good correlation to infarct size assessed by histologic examination and electronmicroscopy.[32] Schaper[33] stated, "The tetrazolium method, when used without reperfusion, becomes discriminative between 3 and 4 hours after coronary occlusion and it can be trusted at about 6 hours after occlusion. With reperfusion, infarcts can be demonstrated after only 20 min of occlusion." Fishbein et al[30] also showed that this technique is valid for localizing irreversibly injured myocardial cells, assessed by cardiac ultrastructure, as early as 3 to 6 hours after coronary occlusion.

The area at risk technique used in the present study is an in vivo technique; that is, it defines a zone of low blood flow at the time of coronary artery occlusion. Since the marker is infused in vivo during coronary artery occlusion, it takes into account coronary collateral blood flow and results in a physiologic perfusion defect of low blood flow much like a thallium scan. This technique has been used in previous studies by this laboratory[35] and in a permanent coronary occlusion model results in a relatively high percentage of necrosis to area at risk.[35] Data derived from in vivo dye injection are similar to those derived from injection of microspheres with subsequent autoradiography.[16] In contrast, risk areas measured by in vitro techiques (injection of barium gel into the coronary arteries or in vitro infusions of dyes down opposite coronary beds simultaneously and under the same pressures) define an anatomic coronary bed at risk that does not take coronary collateral flow into account. We believe that the in vivo technique is more physiologic and more accurately reflects the status of the coronary vasculature as it might occur in man during an acute occlusion, because coronary perfusion pressure distal to the occlusion is always less than that in the nonoccluded bed. Furthermore, we have found that when both in vivo and in vitro techniques are assessed in the same animal,[36] the extent of necrosis is more closely defined by the in vivo rather than the in vitro risk region. The ratio of area of necrosis to area at risk was always lower when the in vitro technique was used. Hence, the in vitro area at risk may actually overestimate the amount of tissue actually at risk for developing necrosis.

In conclusion, although ischemic myocardium can be reperfused by thrombolysis in an emergency setting in many patients with evolving myocardial infarction, a significant delay is unavoidable before thrombolysis is achieved, particularly when the thrombolytic agent is administered by the intracoronary route. The onset of irreversible injury may be delayed by early therapy with a calcium channel blocker, and this may enhance the salvage of tissue at the time of later reperfusion. However, when *both* the administration of the calcium channel blocker and reperfusion are delayed beyond a critical point, the drug is unlikely to enhance the quantity of myocardium salvaged by reperfusion.

Sudden Death and Experimental Acute Myocardial Infarction

YVETTE TROLESE-MONGHEAL, PhD, PIERRE DUCHENE-MARULLAZ, MD,
JEAN-FRANCOIS TROLESE PhD, MICHEL LEINOT,
JEAN-CLAUDE LAMAR PhD, and PIERRE LACROIX, PhD

Acute myocardial ischemia was produced by ligature of the anterior descending coronary artery on 658 dogs in 3 separate laboratories. Overall, 12% of the dogs died within the first hour (instantaneous death) and 25% within the first 24 hours (sudden death). The sudden death rate was significantly related to the logarithm of the weight of the dogs in the range studied. It varied widely if values from small series, comprising the same number of dogs, were considered. Values became less dispersed as the size of the series increased. In series of 10 dogs, sudden death rates ranged from 0 to 70%, whereas in series of 100 dogs the range was 14 to 36%. Stable values were obtained for 50 to 60 dogs per series. Accordingly, reliable assessment of preventive measures can be made only with experimental series of at least this size.

(Am J Cardiol 1985;56:677–681)

Sudden death has been defined by the World Health Organization as death resulting from an event occurring within 24 hours of the onset of an acute episode. Death within 1 hour of the onset of an acute event is called instantaneous death. This distinction is not always clearly made. In industrialized countries, 1,500 persons per million inhabitants die suddenly each year. Sudden cardiac death remains the "major challenge confronting contemporary cardiology." [1] Accordingly, much research has been done in this area.[2–4] The development of drugs with efficient preventive properties relies on the availability of suitable experimental models. Among those proposed by Moore and Spear,[5] the model that comes closest to human pathologic conditions appears to be acute ischemia created by ligature of a coronary artery.

Ligature of the anterior descending coronary artery in the dog sometimes brings about immediate rhythm disorders, and in some cases fatal ventricular fibrillation. Surviving dogs later display ventricular arrhythmia, which peaks 17 to 24 hours after arterial occlusion. This period is usually chosen for the study of antiarrhythmic agents. However, some investigators have used this model to study preventive treatment using pharmacodynamic drugs, although under these conditions, mortality is somewhat haphazard.[6] Most experimental series are too small to allow valid statistical treatment, so the experimental results are of limited value. The aim of this work was to determine the size of the experimental group required to obtain reproducible results, and thereby to determine the number of dogs needed to assess confidently the preventive value of a pharmacodynamic agent with regard to sudden death resulting from coronary occlusion. Sudden and instantaneous deaths were distinguished, and any influence of weight and sex, and of season on mortality was sought.

Methods

This work involved 658 mongrel dogs of either sex. One-stage coronary ligature was carried out using an identical procedure initially developed in laboratory I (Clermont-Ferrand) and extended to laboratory II (Rennes) and laboratory III (Riom). One hundred forty-eight dogs (mean weight

TABLE I Effects of Coronary Ligature in the Dog During the First 24 Hours

Laboratory I—Clermont-Ferrand; II—Rennes; III—Riom. n = number of dogs.

15.7 ± 0.3 kg) underwent operation in laboratory I, 303 (19.6 ± 0.3 kg) in laboratory II and 207 (11.2 ± 0.1 kg) in laboratory III. The study lasted about 5 years.

A tracheal intubation was performed under general anesthesia (sodium pentobarbital, 6 mg/kg, and chloralose, 80 mg/kg, i.v.). Each dog was artificially ventilated with room air (Braun pump). The thorax was opened in the fourth left intercostal space. After incision of the pericardium the heart was placed in a pericardial cradle to facilitate dissection of the anterior descending coronary artery, which was tied in 1 stage 1 cm from its root. The pericardial cradle was then detached, the pericardium closed with a few stitches, and the thorax finally stitched up in 3 planes.

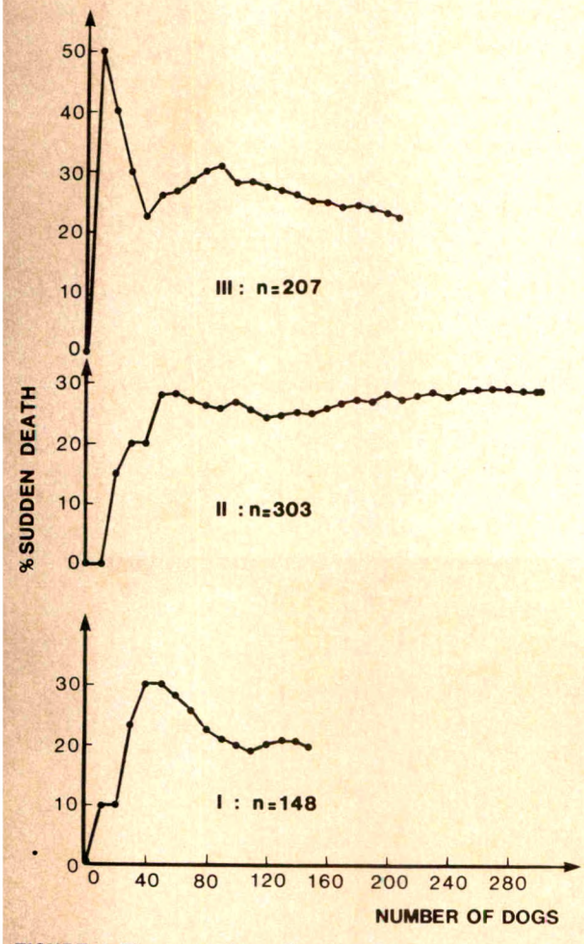

FIGURE 1. The percentage of sudden deaths is proportional to the logarithm of the weight of the dogs: % = 52.85 log weight − 40.76. The regression line was calculated from the percentages of sudden death (**dots**) observed for the following weight ranges: 5 ≤ weight (kg) <13; 13 ≤ weight (kg) <21; 21 ≤ weight (kg) <29; 29 ≤ weight (kg) ≤41.

The variability of occurrence of sudden death was studied as follows. First, the death rate in ligatured dogs was calculated as a percentage in each of the 3 laboratories for the first 10 dogs, the first 20 dogs, the first 30 dogs, and so on. Then, the minimum, maximum and mean death rates were calculated as percentages for experimental series containing 10, 20, 30, and so on, up to 100 dogs successively ligatured. The series were made up by taking the first dog operated on as dog 1 in series 1, the second dog operated on as dog 1 in series 2 and so on. For example, in the first study (laboratory I, 148 dogs) there were 139 series of 10 dogs, 129 series of 20 dogs, and so on. Finally, the confidence intervals determining the theoretical number of survivors needed to indicate that a drug being tested has preventive action, were calculated as a function of the number of animals per series.

The statistical calculations were carried out, depending on the case, by the Student t test in unpaired series, and by 1-factor analysis of variance. Comparison of percentages was made by calculation of reduced deviations.

Results

Study of death rate: Death rates are listed in Table I. Of the whole set of 658 dogs, 82 (12%) died within the first hour (instantaneous death). Instantaneous death rates were not significantly different among the 3 laboratories: 10%, 12% and 15% in laboratories I, II and III. One hundred sixty-two dogs, (25%) died within the first 24 hours (sudden death). Sudden death rates in laboratory I (20%) and laboratory II (29%) differed significantly, but not between laboratory III (22%) and either of the 2 laboratories.

Complete absence of rhythm disorders 24 hours after ligature was observed, on average, in 4% of the total population and in 5% of the surviving dogs. Distribution among the 3 populations varied widely; 3%, 0.3% and 9% of all the dogs, and 4, 0.4 and 11% for surviving dogs in laboratories I, II and III, respectively.

Influence of weight: The influence of weight was studied for the dogs involved in the experiments in laboratories I and II only. Of the 451 dogs considered (mean weight 18.4 ± 0.3 kg), 116 died within 24 hours of ligature. There was a significant difference between the mean weight of the surviving dogs (17.7 ± 0.3 kg) and that of the dogs that died suddenly (20.6 ± 0.5 kg). In general, the percentage of sudden death cases is proportional to the logarithm of the weight of the dogs: % = 52.85 log weight −40.76 (Fig. 1). The difference in the percentage of sudden death between laboratories

TABLE II Study of Death Rate: Percentages According to Sex

TABLE III Study of Death: Percentages According to Season

Season	I			II			III			Total		
	Operated Dogs	Died	%	Operated Dogs	Died	(%)	Operated Dogs	Died	%	Operated Dogs	Died	%
Winter	38	10	26	53	14	26	47	13	28	138	37	27
Spring	47	8	17	102	25	24	48	9	19	197	42	21
Summer	24	4	17	67	29	43	58	14	24	149	47	31
Autumn	39	7	18	81	19	23	54	10	20	174	36	21

Laboratory I—Clermont-Ferrand; II—Rennes; III—Riom.

I and II would be a result of the difference in the weight of the dogs: respectively, 15.7 ± 0.3 kg and 20% sudden death, and 19.6 ± 0.3 kg and 29% sudden death.

Influence of gender: Gender had no influence on death rate (Table II).

Influence of season (Table III): Season did not affect death rate in the series of laboratories I and III. However, in laboratory II, death rate in dogs operated on in summer was significantly different from that in dogs operated on in autumn and spring. The weight of the dogs is irrelevent; the mean weight of the 67 dogs operated on in summer was 21.9 ± 0.6 kg and that of the 81 dogs operated on in autumn was 21.8 ± 0.7 kg.

Variability of occurrence of sudden death: *Death rate as a function of the number of dogs successively operated on* (*Fig. 2*): For the first 10 dogs ligatured, the percentage death rate varied widely: 10% for laboratory I, 0% for laboratory II and 50% for laboratory III. From the 30th dog, this variable tended to become stable. Thus, for laboratory I, from the 30th to the 148th dog, the percentage varied between 19 and 30% (mean 20%). In laboratory II, from the 30th to the 303rd dog, the death rate varied between 20 and 29% (mean 29%). In laboratory III, from the 30th to the 207th dog, the death rate varied from 22 to 31% (mean 22%). Overall, the death rate varied between 19 and 31% from the 30th dog onward.

Variability of the death rate as a function of the number of dogs per experimental series (*Table IV*): After coronary ligature performed successively on series of 10, 20, 30, and so on, up to 100 dogs, the spread of the percentage of sudden deaths narrowed as the number of dogs per series increased. Thus, for series of 10, 50 and 100 dogs, the spread was, respectively, 0 to 70%, 8 to 32% and 14 to 23% in laboratory I, 0 to 60%, 18 to 38% and 22 to 36% in laboratory II, and 0 to 50%, 12 to 38% and 15 to 28% in laboratory III.

Overall, from 50 to 60 dogs per series onward, minimum death rates stabilized between 8 and 14% and maximum death rates between 38 and 35%.

Number of survivors theoretically necessary to demonstrate preventive action of a drug (Table V): This variable was calculated for $p = 0.05$ and $p = 0.001$ as a function of the number of dogs per series. For $p = 0.05$, no significant result is possible from a group of only 10 dogs. At least 40 dogs per group are needed to assess preventive activity confidently.

Discussion

The death rate in dogs after ligature of the anterior descending coronary artery reportedly varies from 0 to 50% (Table VI). However, the number of dogs involved has usually been small, which explains the wide spread. Michelson et al[6] mentioned the wide variability of occurrence of ventricular fibrillation 30 minutes after ligature in 90 dogs with mean death rate 37%. Grimal et al[11] found a 22% death rate after 24 hours in dogs in which 1-stage ligature had been performed (93 dogs), and a 20% death rate when ligature had been carried out in 2 stages (218 dogs) as advocated by Harris and Kokernot.[17]

Wide disparity of results owing to an insufficient number of dogs was evident. Death rate among the first

Michelson et al[21]	10	0 (2 hours)

10 dogs to be ligatured was 10% in laboratory I, 0% in laboratory II and 50% in laboratory III. Overall, for series of 10 dogs sudden death rate can vary from 0 to 70% and for series of 20 dogs from 5 to 55%.

This disparity readily explains the wide variability of results reported for preventive activity assessment of drugs. Yenikomshian and Lown[22] claimed that lidocaine had an antifibrillatory effect. They observed, in 18 dogs treated with lidocaine, a 33% fibrillation rate, compared with 72% in 18 control dogs. This result was not reproduced by Marshall and Parratt,[13] who observed a 34% death rate in 14 control dogs and a 25% death rate in 12 dogs receiving treatment. Similarly, Naito et al[23] found a 49% death rate in 61 controls and 37% in 19 treated animals. Similar results were observed with amiodarone treatment. Chew et al[15] reported an antifibrillatory effect of amiodarone. They found a 29% ventricular fibrillation rate in 14 control dogs and a 9% rate in 11 treated dogs. However, Naito et al[23] found a 44% death rate in 18 treated dogs and a 49% rate in 61 controls. In view of these results, the validity of the positive results reported for bepridil[24] (20 controls, 10 treated dogs), propranolol[16] (24 controls, 24 treated dogs), and the comparison of phenytoin and bretylium tosylate[22] (18 controls and, respectively, 10 and 12 treated dogs) may be doubted. Using 15 controls and 15 treated dogs, Davis and Bigger[14] attempted to evidence an increase in sudden death rate due to thioridazine.

In conclusion, for reliable assessment of potential preventive agents for sudden death, at least 50 dogs per experimental series are essential. Dogs of similar weight should be chosen because larger dogs are more vulnerable to ventricular fibrillation than smaller ones. Gender appears irrelevent; season may have a slight effect on death rate.

Effect of Pulmonary Artery Distention on Systemic Vascular Resistance in Newborn Lambs

JAY M. MILSTEIN, MD, and BOYD W. GOETZMAN, MD, PhD

Balloon distention of the left pulmonary artery (PA) was produced in 14 lambs (aged 1 to 3 days) to assess whether an increase in systemic vascular resistance results from such distention. The lambs were anesthetized with chloralose and instrumented to enable measurement of systemic blood flow, PA pressure, aortic pressure, heart rate and right atrial pressure. PA distention resulted in an increase in systemic vascular resistance and aortic pressure ($p < 0.05$). This result was probably due to a systemic vasoconstrictor response, since systemic blood flow and right atrial pressure did not change significantly. Limited trials using autonomic blocking agents suggested that the response is either a reflex under autonomic control or a response to humoral release of α-adrenergic substances. In conclusion, some interdependence appears to exist between the systemic and pulmonary vascular beds. It is postulated that such changes may be important in fetal life when they may affect redistribution of cardiac output during adaptation to hypoxemia.

(Am J Cardiol 1985;56:681–684)

Distention of the pulmonary artery (PA) results in a significant increase in PA pressure distal to a distending balloon in animals and in humans.[1–3] In addition, distention of the PA of adult animals causes variable reflex effects on the systemic circulation.[4,5] Increased systemic vascular resistance (SVR) has been observed[6–8] in some infants with persistent fetal circulation, a syndrome of central cyanosis due to extrapulmonary right-to-left shunting, caused by pulmonary hypertension.[9–11] This study establishes whether acute PA distention can cause increases in SVR in newborn lambs.

Methods

Studies were performed in 14 newborn lambs (aged 1 to 3 days). The lambs were anesthetized with intravenous alpha chloralose (40 mg/kg body weight), underwent tracheotomy, and were ventilated with a Harvard animal ventilator. Arterial blood gases were maintained in the physiologic range (pH 7.35 to 7.45, P_{O_2} 60 to 90 torr, P_{CO_2} 35 to 45 torr). A left thoracotomy was performed and the ductus arteriosus was isolated and divided. Dissection of tissues surrounding the main PA and its bifurcation was minimized to avoid disruption of sur-

rounding neural elements. The lambs were instrumented to enable measurement of systemic blood flow, using an electromagnetic flow probe on the ascending aorta, and aortic and right atrial pressures using fluid-filled catheters. The flow probe was positioned to avoid impingement on the PA. In addition, an end-hole cuffed balloon catheter was placed in the main PA and advanced to place the balloon in the left PA to enable distention along with PA pressure measurement distal to the balloon. Balloon position was confirmed by palpation.

The flow probes were calibrated using standard flows of normal saline solution generated by a roller flow pump and measured with a graduated cylinder. The pressure transducers were calibrated using a mercury manometer. The 0 reference was taken at the midchest level with lambs in a lateral decubitus position.

The flow and pressure signals were recorded on a Hewlett-Packard eight-channel strip-chart recorder for inspection and calibration purposes. The mean analog flow and pressure signals were processed by an analog-to-digital converter of a microcomputer system (IMSAI 8080), which increased the sensitivity of our system 5-fold. Resistance calculations were performed using the classic equation for resistance where SVR is equal to the mean aortic pressure minus the mean right atrial pressure divided by the mean systemic blood flow. Results were displayed on a video monitor every 0.5 second.

Normal saline solution (1 to 1½ ml) was used to inflate the catheter balloon for 2 to 5 minutes to distend the left PA. The maximal changes in mean PA pressure, mean aortic pressure, mean right atrial pressure, mean systemic blood flow and SVR were assessed using the baseline and peak changes tabulated from the video monitor. Results are expressed as mean ± standard deviation. Statistical analysis was performed using 2-tailed paired t tests with each lamb serving as its own control.

We performed limited trials using α- or β-autonomic blockade or vagotomy in responsive lambs to establish whether the observed changes were under reflex autonomic control. In 1 lamb, after assuring adequate β-adrenergic blockade, distention of the PA was repeated. Adequate blockade was confirmed using a heart rate dose-response curve to isoproterenol with subsequent blockade with propranolol. This was followed by right and left vagotomies. In 2 additional lambs, after assuring adequate α-adrenergic blockade, distention of the PA was repeated. Adequate blockade was confirmed using blood pressure dose-response curves to norepinephrine with subsequent blockade with phenoxybenzamine.

Results

During 48 trials (1 to 7/lamb), distal PA pressure increased with no decrease in systemic blood flow. Additional trials in which distal PA pressure, heart rate or systemic blood flow decreased were not included in the

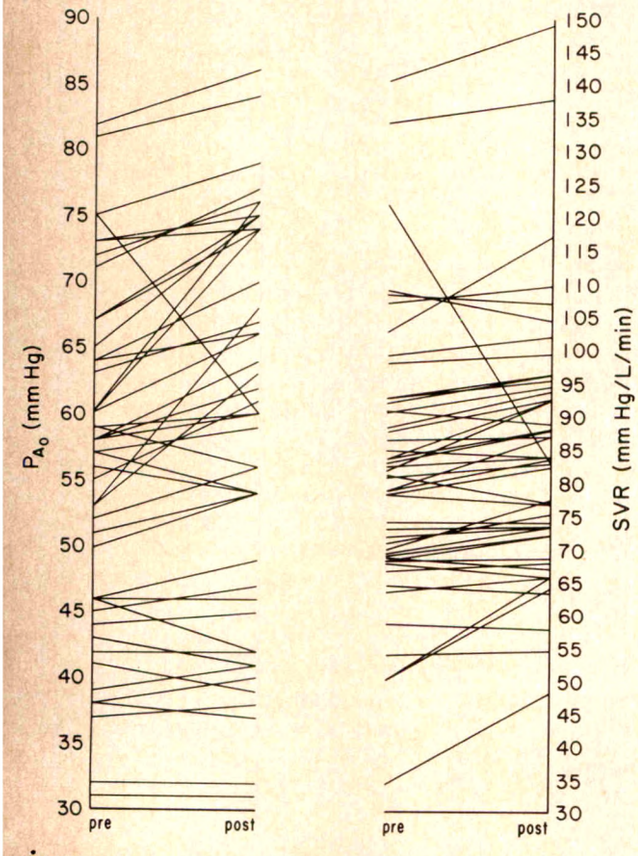

FIGURE 1. Paired pre- and postaortic pressure (PA_0) and systemic vascular resistance (SVR) changes after balloon distention of the pulmonary artery in 48 trials are connected by **solid lines.** Identical data are present in several pairs of PA_0 changes; thus, only 46 lines appear. In 1 trial performed before baseline stabilization, the paired aortic pressure and paired SVR changes decreased strikingly. Four subsequent trials in the same preparation showed increases in 2 and decreases in 2 in PA_0 and SVR from the stabilized baseline. The data were all included in the paired data analysis. The decreases in the latter 2 trials as well as in other trials were less striking and were attributed to biologic variability.

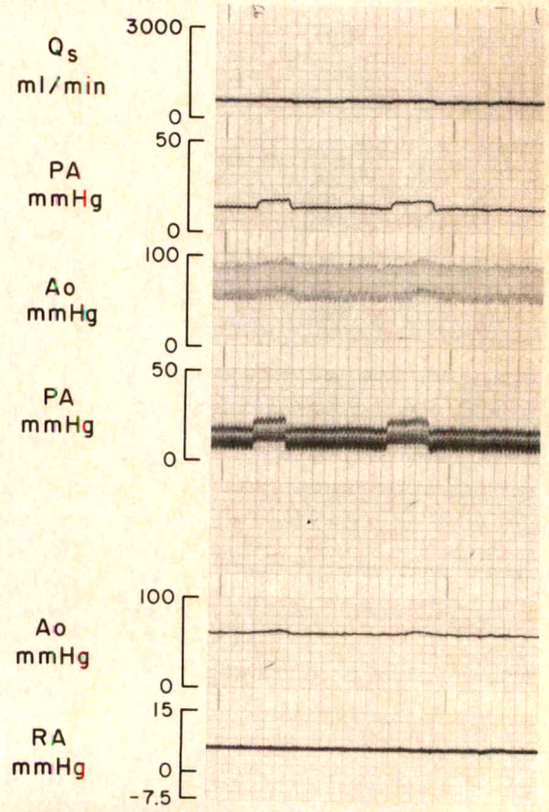

FIGURE 2. Pressure and flow tracings from 1 lamb subjected to left pulmonary artery balloon distention. The distal pulmonary artery pressure (PA) and aortic pressure (Ao) increased and systemic flow (Qs) and right atrial pressure (RA) did not change. Both pulsatile and mean aortic and pulmonary artery pressure tracings are recorded.

analysis because these were interpreted to indicate PA obstruction. After distention of the PA, SVR and aortic pressure increased significantly when the data were analyzed by paired t tests ($p < 0.05$) with each lamb serving as its own control (Fig. 1). However, mean SVR (81.8 ± 20 mm Hg/liter/min to 84.4 ± 19 mm Hg/liter/min) and mean aortic pressure (55.5 ± 13 mm Hg to 58.2 ± 15 mm Hg) did not change significantly because of the wide variation between lambs. The mean baseline systemic blood flow was 0.69 ± 0.3 liters/min and the mean right atrial pressure was 2.7 ± 2 mm Hg. Changes in these variables after PA distention were not statistically significant (Fig. 2).

The baseline mean distal PA pressure of 18.9 ± 7 mm Hg increased to 25.6 ± 9 mm Hg ($p < 0.05$). Pulmonary vascular resistance was not assessed because left atrial pressure and pulmonary blood flow were not measured.

In the lamb treated with β blockade, after distention of the PA, the systemic vascular response persisted. Right vagotomy did not obliterate the response, but a subsequent left vagotomy did. In the additional lambs treated with α blockade, incomplete blockade was initially present (Fig. 3). Once complete blockade was confirmed, PA distention did not result in SVR changes. In addition, the distal PA pressure changes were blocked (Fig. 4).

Discussion

Acute PA distention caused increases in SVR in newborn lambs, which appeared to be a result of systemic arterial vasoconstriction since systemic flow and right atrial pressure did not change.

Our findings are similar to those observed by others in anesthetized adult dogs subjected to balloon distention of the pulmonary trunk.[5] In other studies reporting variable responses in systemic arterial pressure, resistance changes were not calculated.[4] The latter investigators found the responsible baroreceptors to be much more concentrated in the pulmonary arterial branches than in the main PA.[12] This is consistent with our experience. In another study, both conscious and anesthetized dogs were evaluated.[3] A small increase in

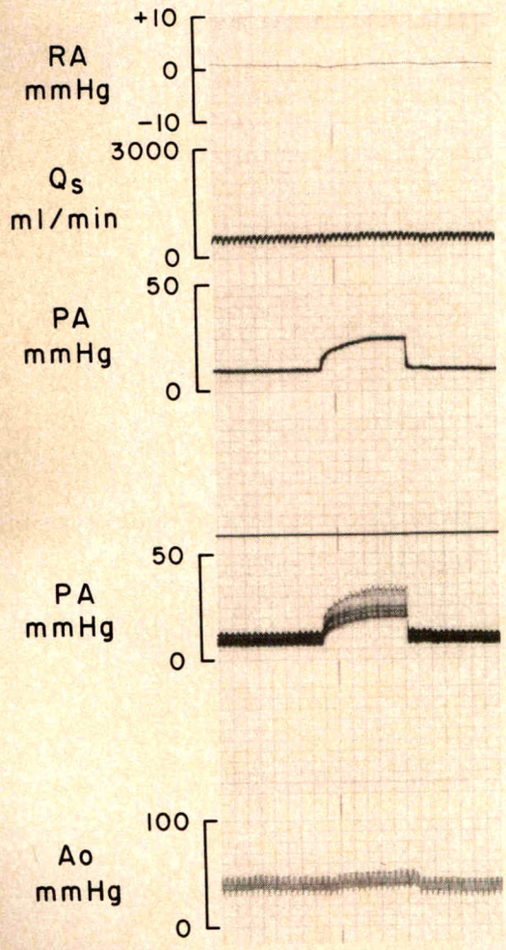

FIGURE 3. Right atrial (RA), pulmonary artery (PA) and aortic (Ao) pressure and systemic flow (Qs) tracings from a lamb treated with phenoxybenzamine before left pulmonary artery balloon distention. Incomplete blockade is present with persistent aortic pressure changes.

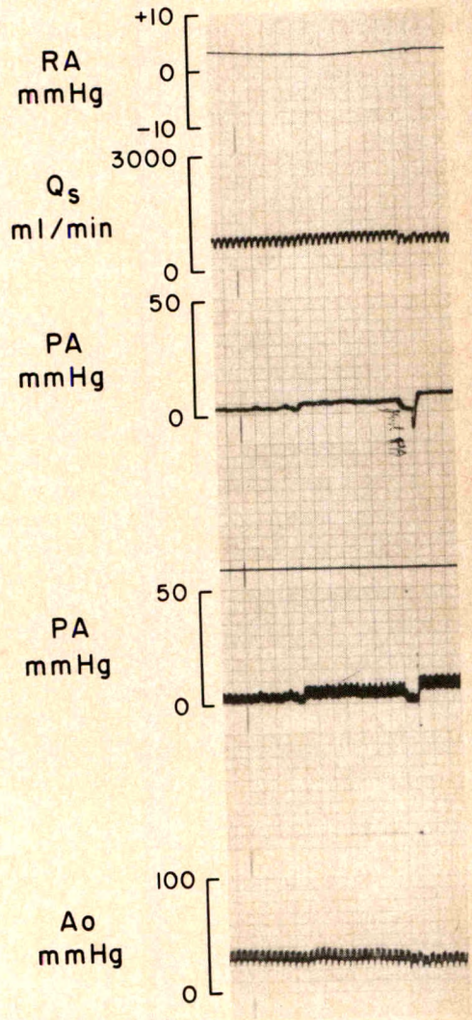

FIGURE 4. Right atrial (RA), pulmonary artery (PA) and aortic (Ao) pressure and systemic flow (Qs) tracings from the same lamb as in Figure 3. The distal pulmonary artery and aortic pressure changes are obliterated after administration of an additional dose of phenoxybenzamine. In addition, substantial vasodilation has developed, accounting for the decreases in aortic and pulmonary artery pressures.

aortic pressure was observed in response to balloon distention in the main PA, yet the calculated SVR did not change.[3] However, diastolic aortic pressure, which correlates with SVR,[13,14] increased significantly, suggesting that changes in SVR escaped detection. Finally, unanesthetized sheep, including newborns, 3-month-old lambs and adult sheep have been evaluated during balloon distention of the proximal main PA. The adult sheep had small but significant increases in aortic pressure, whereas the newborns did not.[2] The investigators implied that SVR did not change, yet the cardiac output decreased significantly. Consequently, SVR must have increased in order to maintain the elevated or constant aortic pressure observed.

The variable findings just described may be a result of biologic variability or of effects of anesthesia. Alpha chloralose was used as the anesthetic in our studies because it has been shown to have less severe depressant effects on ventricular performance and greater preservation of reflex activity, particularly baroreceptor reflexes, in some species.[15,16] Whether the increase in SVR would be enhanced using an unanesthetized preparation remains to be determined.

Our finding that acute PA distention causes increases in pulmonary arterial pressure is similar to observations by other investigators.[1–3] The pulmonary effects have not been abolished by vagotomy,[17] but can be blocked with lidocaine infiltration of the main PA, by the infusion of 6-hydroxydopamine, which causes selective destruction of adrenergic nerve terminals and depletion of norepinephrine, or by surgical denervation of the pulmonary artery. Apparently, the pulmonary vasoconstrictive mechanism primarily involves the release of norepinephrine at nerve endings.[17] Our findings of blocked PA pressure changes in limited trials with α-adrenergic blockade are also consistent.

The pulmonary vasoconstrictive mechanism may have several roles. In the fetus, hypoxemia enhances pulmonary vasoconstriction. This, in turn, may lead to distention of proximal segments of the PA, which results in further pulmonary vasoconstriction, preferentially shunting blood across the ductus arteriosus to the placenta. After birth, as the pulmonary vascular resistance decreases with lung expansion and improved oxygenation, PA distention may diminish, resulting in still further increases in pulmonary blood flow.

The role of the autonomic nervous system in systemic vascular changes has also been studied in adult animals. Systemic effects can be blocked with vagotomy,[4] as well as local infiltration of the main PA with phentolamine or 2% lidocaine.[5] Our results with limited trials using autonomic blocking agents and vagotomy are similar to those of others.[4,5,17] However, we cannot conclude whether the proposed norepinephrine release into the circulation is more critical than autonomic nervous control in the changes observed.

Some interdependence appears to exist between the systemic and pulmonary vascular beds, which can be triggered in newborn lambs by distention of the pulmonary artery distal to its bifurcation. Although the physiologic role of the systemic vasoconstrictor response is unclear, it could be important in the redistribution of cardiac output observed in the hypoxemic fetus.

Cardiac Bioprostheses

Proceedings of the Second International Symposium
Rome, Italy, May 17-19, 1982

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $69.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

HEWLETT-PACKARD'S NEW PAGEWRITER:

S I M P L E

Take a look at our new HP 4760 PageWriter Cardiograph. It's small, clean, simple. Yet, this unassuming package has the ability to meet all your ECG needs. Because it's easy to upgrade, from basic alphanumeric to measurement to interpretive. It's also easy to use. Operator prompts tell you about poor lead contact so you get an accurate trace the first time. And, you can start or stop printing at any time by pressing a single button. Best of all, PageWriter's small, lightweight design makes it easy to move from place to place.

A C C U R A T E

The new PageWriter is also extremely accurate. Automatic measurement capability means that the last ECG of the day is as accurate as the first. No more inconsistent, manual calculations. Plus, you can count on the analysis program in the interpretive module. It's the same one used worldwide by our customers to analyze over 5 million ECG's each year.

V E R S A T I L E

The basic PageWriter can be configured in a number of ways to handle just about any ECG application need. Order your PageWriter to meet today's applications. Then, field-upgrade your PageWriter when your needs change. Add automatic measurement. Add diagnostic interpretation. You can see how the PageWriter adapts. To any area of your hospital. To any ECG need.

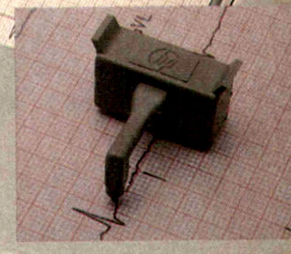
A V A L U E

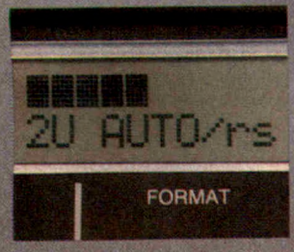
Simplicity. Accuracy. Versatility. Legendary HP reliability, service and support. Things you might expect from a high-priced cardiograph. But, the PageWriter is affordable. In fact, it's simply the best value in a cardiograph today.

Call **800-952-2212** and ask for our special "demo" PageWriter brochure. Or, write Hewlett-Packard Company, McMinnville Division, 1700 South Baker Street, McMinnville, OR 97128.

HEWLETT PACKARD

SIMPLY THE BEST VALUE IN A CARDIOGRAPH TODAY.





*1985 HEWLETT-PACKARD

Initial therapy should start on the right course.

hypertensive patients

Minipress® for initial therapy
(prazosin HCl)

- Is effective when used alone
- Does not cause a significant incidence of sexual impotence, although it has been reported[1]
- Does not adversely affect blood lipids*[2]
- Does not lower heart rate, cardiac output or work capacity[3]
- Does not induce potassium wasting[1]
- Most common side effects with Minipress, generally mild and transient, are dizziness, headache, drowsiness, palpitations, and nausea. Syncope (sudden loss of consciousness) has been reported in about 0.15% of patients at the recommended initial dose of 1 mg.

*Minipress is not indicated for the treatment of hyperlipidemia.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

for Initial Therapy in Hypertension

Please see Minipress brief summary on following page

© 1983, Pfizer Inc.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

Brief Summary
MINIPRESS® (prazosin hydrochloride) Capsules ***For Oral Use***
INDICATIONS: MINIPRESS (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
WARNINGS: Minipress may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120–160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS. The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution. (See DOSAGE AND ADMINISTRATION.) Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsule of MINIPRESS. The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure; namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS in pregnancy has not been established. MINIPRESS is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS some of them rarely. (In some instances exact causal relationships have not been established.)

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus, alopecia, lichen planus.

Genitourinary: urinary frequency, incontinence, impotence, priapism.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See WARNINGS.)

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

OVERDOSAGE: Accidental ingestion of at least 50 mg of MINIPRESS in a two year old child resulted in profound drowsiness and depressed reflexes. No decrease in blood pressure was noted. Recovery was uneventful.

Should overdosage lead to hypotension, support of the cardiovascular system is of first importance. Restoration of blood pressure and normalization of heart rate may be accomplished by keeping the patient in the supine position. If this measure is inadequate, shock should first be treated with volume expanders. If necessary, vasopressors should then be used. Renal function should be monitored and supported as needed. Laboratory data indicate MINIPRESS is not dialysable because it is protein bound.

TOXICOLOGY: Testicular changes, necrosis and atrophy have occurred at 25 mg/kg/day (60 times the usual maximum recommended dose of 20 mg per day in humans) in long term (one year or more) studies in rats and dogs. No testicular changes were seen in rats or dogs at the 10 mg/kg/day level (24 times the usual maximum recommended dose of 20 mg per day in humans). In view of the testicular changes observed in animals, 105 patients on long term MINIPRESS (prazosin hydrochloride) therapy were monitored for 17-ketosteroid excretion and no changes indicating a drug effect were observed. In addition, 27 males on MINIPRESS (prazosin hydrochloride) alone for up to 51 months did not demonstrate changes in sperm morphology suggestive of drug effect.

HOW SUPPLIED: MINIPRESS is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

More detailed information available on request.

How thorough and unbiased is your drug reference?

If it's not the new 16th edition of MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Editor
Gertrude Dittus Gonzales, R.Ph., B.S., Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

CAN A HOLTER RECORDER WEIGH AS LITTLE AS THESE?

YES...THE NEW "FEATHERWEIGHT" FROM SPACELABS.

INTRODUCING THE SMALLEST, LIGHTEST HOLTER RECORDER AVAILABLE.

The new Spacelabs 90201 Holter recorder weighs just 10 oz., – about the same as some of the everyday items your patients might have in their pockets. And at a tiny 3.2″ × 5.5″ × 0.8″ size, it fits right in a shirt pocket, too.

The latest, most advanced technology has enabled us to put all the reliability, accuracy and capability of our previous generations of Holter recorders – and then some – into this new compact model, for the greatest patient comfort and convenience ever.

It provides 2 channels of ambulatory ECG data, plus a discrete timing track for 24 or 48 hours' continuous recording time. Automatic calibration and a backup internal battery for the LCD clock guarantee accurate event-time correlation. And the patient event marker is easily accessible.

NEW
"FEATHERWEIGHT" 90201 HOLTER RECORDER

Ask your representative for the name of a scanning service in your area.

AND SPACELABS' MOST ADVANCED, ACCURATE, EASY-TO-USE HOLTER ANALYSIS SYSTEM.

Our new 90101 scanner minimizes the inaccuracies inherent in other arrhythmia discriminators via its powerful simultaneous 2-channel discriminator, for more meaningful information. And you can get this information faster and easier than ever before – a full report, including numeric summary, graphic summary and sample beat classification, in just 10-15 minutes – without any operator interaction! Or you can have a fully edited report, using its morphology merge/delete feature, in just 5 minutes. What's more, you can easily program the system to individualize reports to meet your specific needs. It includes an industry standard communications bus – a pathway to the future with the product you purchase today. *And its cost is justified in only 3 scans/month!*

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

EDITED BY

DEAN T. MASON, M.D.
Professor of Medicine and Physiology
Chief, Cardiovascular Medicine
University of California at Davis
School of Medicine and University Medical Center
Davis and Sacramento, California
Editor-In-Chief, AMERICAN HEART JOURNAL

JOHN J. COLLINS, JR., M.D.
Professor of Surgery
Chief, Division of Thoracic and Cardiac Surgery
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Sample Table of Contents:

Section 1 - Stable Angina Pectoris and Asymptomatic Coronary Disease

Section 2 - Variant Angina Pectoris

Section 3 - Unstable Angina Pectoris

Section 4 - Acute Myocardial Infarction

Section 5 - Myocardial Preservation

Section 6 - Pharmacologic and Related Approaches to Coronary Dilatation

Section 7 - Percutaneous Transluminal Coronary Angioplasty

Section 8 - Intracoronary Thrombolysis in Evolving Myocardial Infarction

Section 9 - Long-Term Achievements of Myocardial Revascularization by Medical and Surgical Therapy

Update your echo lab with Cardiac Doppler.

Sonacolor® CD

CARDIAC DOPPLER

The Cardiac Doppler system expands conventional echocardiography by providing noninvasive assessment of flow velocities through all four heart valves. It is all you need to confirm stenotic or regurgitant valvular disease.

- Color spectral patterns grade the degree of valve stenosis and turbulence.
- Valve cross-sectional areas can be derived from pressure gradient half-times.
- Color spectral patterns grade the degree of regurgitation. Valve prolapse is identified through the presence and timing of regurgitation.
- Detects the high velocity jets of flow through prosthetic valves. Detects prosthetic valve leakage. Monitors valve function over time.
- Color spectral patterns locate and grade shunts.
- Displays ECG trace for time reference. Phono trace for correlation of heart sounds with Doppler flow velocity patterns.
- Computes cardiac output approximation, stroke volume and average flow.

Call 1-800-334-4531 to place your order, for in-depth information or an on-site demonstration.

Pharmacokinetics and Pharmacodynamics of Milrinone in Chronic Congestive Heart Failure

JOSEPH R. BENOTTI, MD, LAWRENCE J. LESKO, PhD, JANE E. McCUE, RN, and JOSEPH S. ALPERT, MD

The acute hemodynamic effects and pharmacokinetics of bolus intravenous milrinone administration were assessed in 13 patients with severe congestive heart failure. Serial hemodynamics were measured and blood samples were obtained to determine plasma milrinone concentration and calculation of pharmacokinetic variables after administration of milrinone at 12.5, 25, 50 and 75 μg/kg, allowing at least 6 hours to elapse between consecutive milrinone doses. At each dose milrinone effected prompt but very short-lived increases in cardiac output and left ventricular stroke work and decreases in pulmonary artery pressure, right atrial pressure and systemic and pulmonary vascular resistance in a non-dose-dependent fashion. Pulmonary artery wedge pressure decreased in a dose-related manner. Heart rate increased significantly after the 75-μg/kg dose and mean arterial pressure decreased significantly only after the 50- and 75-μg/kg milrinone dose. The time-dependent decline in plasma milrinone concentration was biexponential and log linear, conforming to an open 2-compartment model of drug distribution and elimination. Mean plasma milrinone clearance (± standard error) was 0.15 ± 0.03 liters/min/kg, volume of distribution was 0.35 ± 0.02 liters/kg and mean elimination half-life was 1.7 hours.

(Am J Cardiol 1985;56:685–689)

Milrinone, a bipyridine derivative, is one of several recently developed nonglycoside, nonsympathetically mediated, positive inotropic agents. Milrinone exerts a positive inotropic effect in vitro as evidenced by an increase in myocardial force generation, an increase in ventricular developed tension and the peak rate of isovolumic ventricular pressure generation (LV dP/dt) in isolated myocardial tissue, isolated heart preparations and laboratory animals.[1–3] Exploratory efficacy studies in patients with advanced congestive heart failure (CHF) show that milrinone administered intravenously and orally improves cardiac index, lowers pulmonary artery wedge and right atrial pressures and dramatically lowers systemic vascular resistance[4,5] while increasing the peak rate of LV dP/dt.[4] Its salutary hemodynamic effects are probably exerted, in part, through an inotropic and vasodilator mechanism of action. Some additional benefit may accrue from the ability of milrinone to improve diastolic ventricular compliance.[6] This study was designed to elucidate the pharmacokinetics and pharmacodynamics of milrinone administered intravenously on an incremental bolus dose schedule.

From the Division of Cardiovascular Medicine, University of Massachusetts Medical Center, Worcester, Massachusetts, and the Pharmacokinetics Laboratory, University of Maryland School of Pharmacy, Baltimore, Maryland. This investigation was supported in part by a grant from the Sterling Winthrop Research Institute, Rensselaer, New York. Manuscript received March 4, 1985; revised manuscript received May 3, 1985, accepted May 13, 1985.

Address for reprints: Joseph Benotti, MD, Division of Cardiovascular Medicine, University of Massachusetts Medical Center, 55 Lake Avenue North, Worcester, Massachusetts 01605.

Methods

According to a protocol approved by the Committee on the Protection of Human Subjects in Research at the University of Massachusetts Medical Center, all consecutive patients with New York Heart Association class III or IV symptoms of CHF and an ejection fraction of less than 0.40 while receiving digoxin and diuretic therapy were candidates for this investigation. Patients were excluded from participation in this protocol if they had (1) myocardial infarction within the preceding 3 months, (2) limitation of exercise capacity by angina rather than by dyspnea or fatigue, (3) untreated sustained ventricular tachycardia, (4) serious primary hepatic or renal dysfunction (serum creatinine 3.0 mg/dl or more), (5) cardiac index greater than 2.5 liters/min/m^2, and (6) pulmonary artery wedge pressure less than 15 mm Hg.

Each patient was maintained on a no-added-salt diet and a stable dose of digoxin and diuretics. Twenty-four hours before milrinone administration, all vasodilator treatment was discontinued. The patient was transferred to the coronary care unit, where a triple-lumen thermodilution Swan-Ganz catheter was advanced into the pulmonary artery. After baseline hemodynamic stability was established (less than 10% variation in cardiac output and pressures on at least 2 consecutive measurements at least 1 hour apart), intravenous milrinone was administered as a 12.5-μg/kg dose at 100 μg/s. Serial hemodynamic measurements and 5-ml blood specimens were obtained to determine plasma milrinone concentration at 5, 10, 15, 30, 60, 180 and 360 minutes after each dose. Six hours after the first dose each patient received milrinone as 25 μg/kg by intravenous bolus at 100 μg/s with serial hemodynamic measurements and blood sampling as previously outlined. After a night of rest the patient received his or her third milrinone dose (50 μg/kg) 24 hours after the 12.5-μg/kg milrinone dose, with serial hemodynamic measurements and blood

TABLE I Hemodynamic Response to Milrinone (n = 13)

* $p < 0.05$ relative to control; † $p < 0.05$ relative to peak response after the 12.5- and 25-μg/kg doses.
C_1–C_4 = control hemodynamic parameters (as defined in text); CO = cardiac output; HR = heart rate; LVSW = left ventricular stroke work; MAP = mean arterial pressure; PAP = pulmonary artery pressure; PAW = pulmonary artery wedge pressure; PVR = pulmonary vascular resistance; RAP = right atrial pressure; SVR = systemic vascular resistance.

sampling for milrinone concentrations obtained as above. The fourth dose, 75 μg/kg was then administered 6 hours after the third dose, again with serial hemodynamic monitoring and milrinone plasma level determinations.

Cardiac output was measured in triplicate by the thermodilution technique. Mean arterial pressure was measured as the electrical integral of the phasic oscilloscopic signal or as the sum of diastolic pressure plus one-third pulse pressure when measured by sphygmomanometer. For all pressures the 0 reference point was taken at 5 cm below the sternal angle. Derived hemodynamic variables were calculated according to standard formulas.[7]

Blood for plasma milrinone concentration determination was collected in citrated tubes, immediately centrifuged and the supernatant (plasma) was frozen at −60°C. Milrinone plasma levels were determined by a high-performance gas liquid chromatography technique.[8] Those analyzing and reporting milrinone plasma levels were not intentionally blinded to milrinone dose, time after dose or hemodynamic responses.

An open 2-compartment model was fitted simultaneously to the plasma milrinone concentration-time data obtained after each successive milrinone dose by nonlinear regression analysis using ADAPT.[9] Model-dependent kinetic parameter values of total body clearance (CL), volume of distribution (V_z) and elimination rate constant (λ_z) were calculated from regression-dependent micro rate constants and volume terms as follows[10]: $CL = k_{10}V_c$; $V_z = CL/\lambda_z$; $\lambda_z = 1/2[(k_{12} + k_{21} + k_{10})] - [(k_{12} + k_{21} + k_{10})^2 - 4k_{21}k_{10}]^{1/2}$.

The terminal elimination half-life ($t_{1/2}$) was calculated as: $t_{1/2} = \ln 2/\lambda_z$.

For each patient at each milrinone dose, hemodynamic variables were measured at the time of the maximal cardiac output. Baseline hemodynamic variables are average values of 2 sets of data recorded one-half hour before and just before drug administration. Comparisons between peak response relative to baseline for each milrinone dose, between consecutive baselines and between peak hemodynamic responses after each milrinone dose were made using an analysis of variance.

Results

Our study population was composed of 10 men and 3 women, aged 43 to 81 years. Eleven had New York Heart Association class IV symptoms and 2 had class III symptoms. CHF resulted from advanced coronary heart disease in 11 patients and from nonischemic dilated cardiomyopathy in 2. The hemodynamic action and kinetic behavior of milrinone in these 2 patients was indistinguishable from those of the 11 patients with coronary heart disease. No patient had responded satisfactorally to digoxin, diuretics and vasodilators in optimal doses. The advanced state of LV dysfunction in each patient was evidenced by a severe depression in LV ejection fraction, ranging from 0.08 to 0.27.

Table I describes the group mean peak hemodynamic responses to the 4 consecutive milrinone doses and the group mean maximal plasma milrinone concentration after consecutive milrinone doses. Cardiac output increased significantly with each dose, to 6.0, 6.0, 6.1 and 6.6 liters/min after the 12.5- 25-, 50- and 75-μg/kg milrinone doses, respectively. Analysis of variance revealed no significant differences between maximal cardiac output after each dose. Pulmonary artery wedge pressure decreased significantly to 17, 13 and 11 mm Hg after milrinone administration at 12.5, 50 and 75 μg/kg,

respectively. The overall tendency was that the percent decrease in wedge pressure increased; 19%, 11%, 35% and 48% after the 12.5-, 25-, 50- and 75-μg/kg milrinone doses. The wedge pressure reduction after the 50- and 75-μg/kg doses significantly exceeded that after the 12.5- and 25-μg/kg milrinone doses, consistent with a dose-response relation. After each dose, milrinone significantly increased LV stroke work in a non-dose-related fashion. Mean arterial pressure decreased slightly but significantly only after the 50- and 75-μg/kg doses. Mean pulmonary artery pressure decreased significantly, from the 30- to 32-mm Hg range, during the control period to 26, 27, 24 and 25 mm Hg, respectively, as the milrinone dosage was increased. No dose-response relation was discernible. Right atrial pressure decreased significantly after milrinone administration, from the 10 to 13 mm during the control period to 9, 8, 6 and 8 mm Hg as the milrinone dosage was increased, with no demonstrable dose-response relation. Systemic vascular resistance decreased significantly, to 13.3, 13.4, 12.3 and 11.2 Wood units after each milrinone dose. The decrease in systemic vascular resistance was dose-independent, as there was no significant difference between systemic vascular resistance values measured after successively larger milrinone doses. Pulmonary vascular resistance, initially slightly elevated, decreased significantly with milrinone administration. No dose-response relation was discernible. Heart rate increased significantly only after the largest milrinone dose.

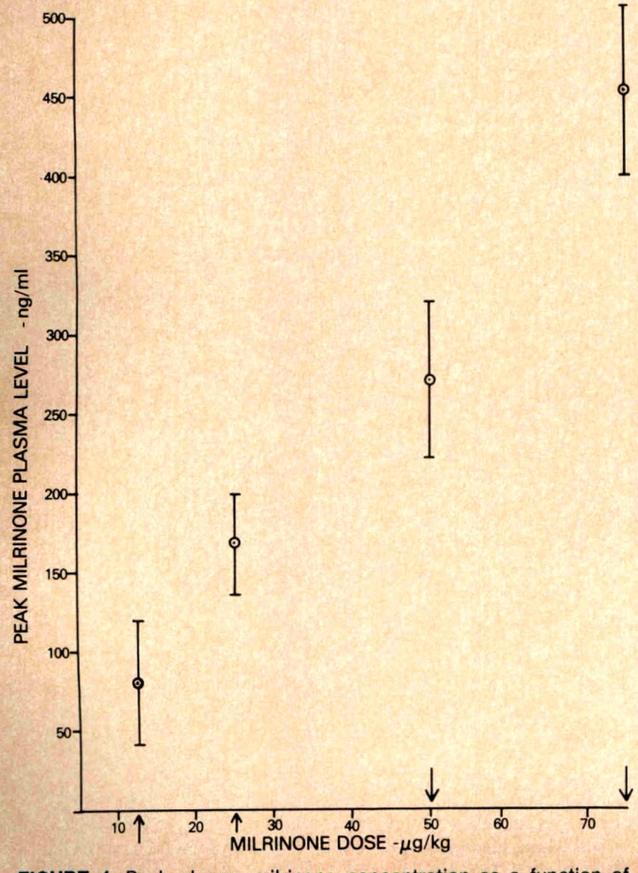

FIGURE 1. Peak plasma milrinone concentration as a function of dose.

The peak hemodynamic response to milrinone occurred at or within 60 minutes of dosing. Hemodynamic measurements returned to baseline values by 90 minutes after drug administration.

Peak plasma milrinone concentration rose linearly with dosage (Fig. 1). No correlation was found between the maximal cardiac output and plasma milrinone concentration (Fig. 2).

Figure 3 is a ventricular function curve in which cardiac output was plotted against pulmonary artery wedge pressure. Because no significant differences were found between the control cardiac output values and pulmonary wedge pressure values preceding each milrinone dose, they were averaged and are represented by point C. $M_{1,2}$ represents mean cardiac output and pul-

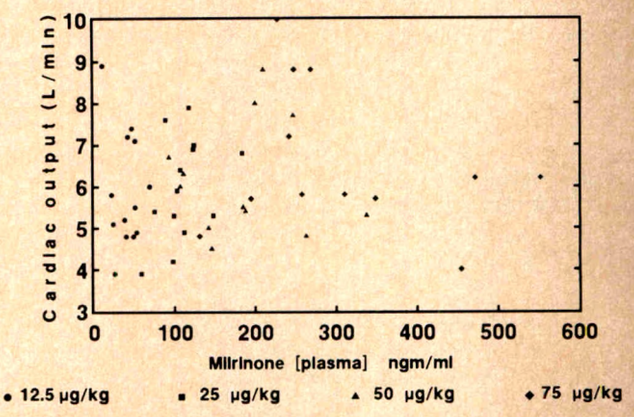

FIGURE 2. Relation between individual maximal cardiac output after each milrinone dose and simultaneous plasma milrinone concentration.

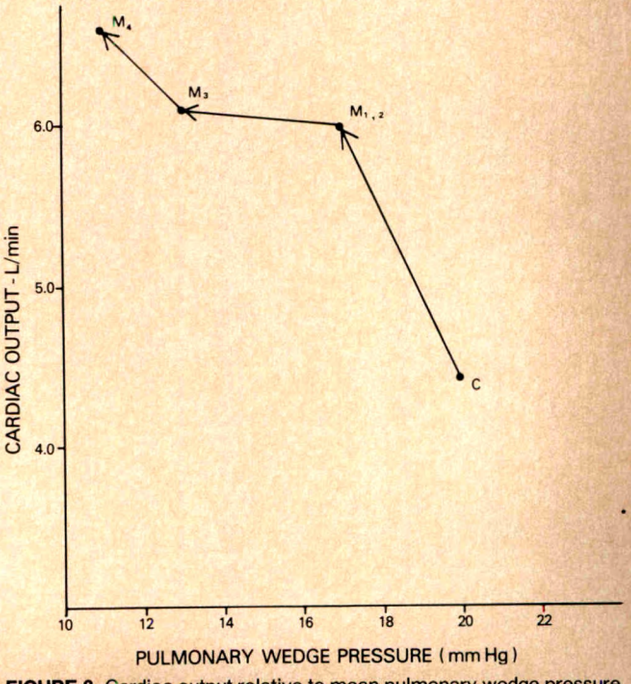

FIGURE 3. Cardiac output relative to mean pulmonary wedge pressure expressed as a function of increasing milrinone dose. See text for details.

monary wedge pressure after milrinone doses of 12.5 and 25 μg/kg and M_3 and M_4 represent cardiac output and pulmonary wedge pressure after doses of 50 and 75 μg/kg. Although the increase in cardiac output plateaus as the milrinone dose increases (Table I) and the individual maximal cardiac output appears to be independent of simultaneous plasma milrinone concentration (Fig. 2), overall ventricular performance (expressed as cardiac output as a function of pulmonary artery wedge pressure) improves as the milrinone dose increases.

Figure 4 shows observed and predicted plasma milrinone concentrations obtained by simultaneous modeling in a representative patient. It shows the close correlation between observed and calculated plasma milrinone concentrations. Plasma milrinone concentration declines biexponentially with time after milrinone injection. The biexponential equation describing the time course of milrinone plasma concentrations preceding the lowest milrinone dose is also shown. A 2-compartment body model adequately described the disposition of milrinone in each patient.

The derived kinetic parameter values for milrinone include a mean CL of 0.15 liters/kg/hour (range 0.11 to 0.20) and a mean V_z of 0.35 liters/kg (range 0.24 to 0.44). The milrinone half-life values ranged from 1.3 to 2.2 hours (mean ± standard deviation 1.7 ± 0.3).

Discussion

This investigation demonstrates that milrinone in incremental intravenous doses up to 75 μg/kg elicits significant but very abbreviated improvements in ventricular function. These are manifested by increases in cardiac output and LV stroke work and decreases in pulmonary artery wedge and right atrial pressure. Systemic vascular resistance decreases significantly, heart rate increases significantly and blood pressure decreases only with the highest milrinone dose. The salutary hemodynamic changes are compatible with an inotropic and vasodilator mechanism of action. Baim et al[4] and Collucci et al[13] published preliminary data that suggests that milrinone exerts its beneficial hemodynamic effect, at least in part, by a positive inotropic action. In vitro and experimental animal data also suggest that milrinone has an inotropic mechanism of action.[1–3]

The explanation for the pleateau relation between milrinone dose and hemodynamic response is not clear. As ventricular function improves with milrinone, a drug that exerts its beneficial effects through a nonglycoside, noncatecholamine-mediated mechanism of action,[1–3] evoked hemodynamic changes may work in concert to attenuate further functional improvement despite further dosage increases. Cardiac preload may be reduced as a result of reflex withdrawal of venular tone or overall hemodynamic improvement, or owing to a direct dilatory effect of milrinone on venous smooth muscle. In this manner, milrinone may redistribute blood away from the central circulation, thereby reducing LV end-diastolic volume. This would limit the maximal increase in cardiac output attainable. Indeed, our data suggest that higher doses of milrinone (50 and 75 μg/kg) reduced pulmonary artery wedge pressure to

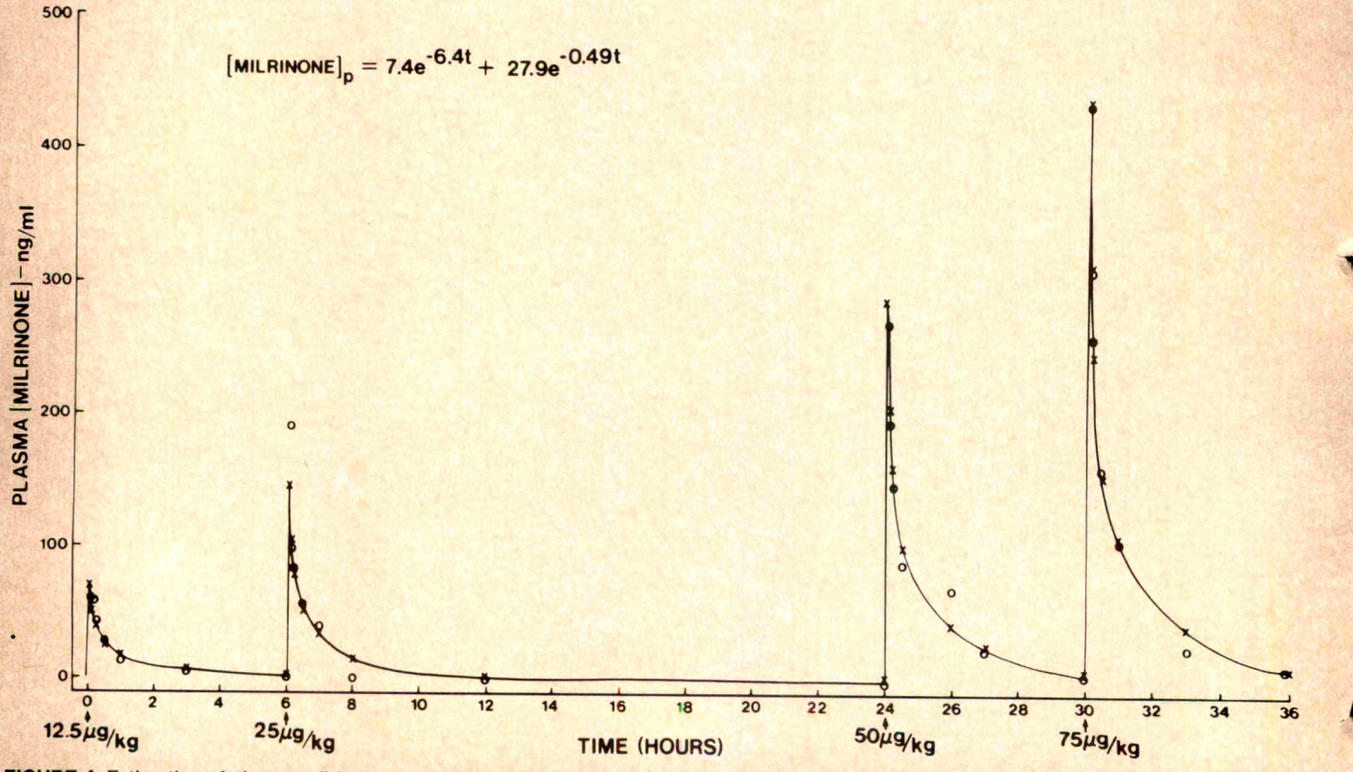

FIGURE 4. Estimation of plasma milrinone concentration for repetitive doses in a representative patient using the "Adapt" program for multiple dosing. Close agreement between the computer-derived curve (drawn from estimated milrinone plasma levels [x]) with the measured milrinone plasma levels (**open circles**) is apparent.

a greater degree than lower milrinone doses (12.5 and 25 μg/kg). As the wedge pressure declines below 15 mm Hg in most patients with CHF, it is likely that any further decline in preload would limit subsequent increase in cardiac output effected by further improvements in the inotropic state of the myocardium or decreases in afterload effected by a larger milrinone dose. The plateau relation between milrinone dose and hemodynamic response may also be explained by milrinone's presumed mechanism of action as a phosphodiesterase inhibitor. Doses of milrinone in excess of that required for maximal phosphodiesterase inhibition should effect little, if any, additional hemodynamic improvement. These data suggest that there is a plateau in the response to bolus milrinone administration in doses in excess of 50 to 75 μg/kg/min. Higher doses may cause an undesirable increase in heart rate or decline in mean arterial pressure without further improving cardiac output.

The characterization of milrinone disposition by a 2-compartment open model after repeated intravenous bolus administration is in agreement with the observations of Stroshane et al.[11,12] They reported a similar disposition profile in patients with CHF and in normal volunteers. Their CL (0.11 ± 0.01 liters/kg/hour) in patients with CHF was similar to the mean CL (0.15 liters/kg/hour) found in this study. The volumes of distribution in CHF were very similar (0.33 vs 0.35 liters/kg). Because of almost identical CL and V_z parameter values in each study, the terminal elimination half-life values in their study (1.8 hours) and our study (1.7 hours) were identical. By contrast, they found that the elimination half-life of milrinone in normal volunteers was markedly less, 0.8 hours, primarily owing to a faster CL (90.28 liters/kg/hour) and not because of a smaller distribution volume. A major question that must be addressed is whether plasma clearance of milrinone increases and its elimination half-life shortens as cardiac function improves.

Relative to dopamine or dobutamine, milrinone has a longer elimination half-life. Accordingly, a loading bolus followed by a continous intravenous infusion is required to achieve a prompt, therapeutically effective steady-state plasma level. However, the elimination half-life of milrinone (1.7 to 1.8 hours) is short enough that the plasma concentration should promptly decrease following discontinuation of intravenous infusion. Accordingly, any potentially undesirable hemodynamic effects should resolve reasonably promptly with dose reduction or drug discontinuation.

Effects of Hydralazine on Pressure-Volume and Stress-Volume Relations in Congestive Heart Failure Secondary to Idiopathic Dilated Cardiomyopathy

MARK L. SMUCKER, MD, C. FAGG SANFORD, MD, and KIRK M. LIPSCOMB, MD

The mechanism by which hydralazine improves cardiac function in patients with heart failure is not well characterized. Hydralazine may improve left ventricular (LV) function by decreasing afterloading wall stress or by increasing myocardial contractility. The effect of intravenous hydralazine was assessed in 8 patients with severe idiopathic dilated cardiomyopathy. Hydralazine increased stroke volume index (from 24 ± 8 to 40 ± 9 ml/m², p <0.01) and decreased systemic vascular resistance (from 1,603 ± 619 to 810 ± 317 dynes s cm^{-5}, p <0.01) and peak LV wall stress (from 476 ± 118 to 410 ± 68 kdynes/cm², p = 0.02). Two groups were defined by normal or high LV wall stress. Patients with high LV stress had higher LV end-diastolic pressure (38 ± 12 vs 17 ± 8 mm Hg, p <0.01), LV end-diastolic volume index (184 ± 24 vs 149 ±7 ml/m², p <0.01) and systemic vascular resistance (1,423 ± 686 vs 846 ± 293 dynes s cm^{-5}, p = 0.01). Hydralazine decreased stress more in these patients (−101 ± 57 vs −6 ± 9 kdynes/cm², p = 0.02), LV end-diastolic pressure (−12 ± 7 vs 2 ± 2 mm Hg, p = 0.02), systolic pressure (−15 ± 13 vs 3 ± 4 mm Hg, p = 0.03) and systemic vascular resistance (−1,053 ± 247 vs −363 ± 83 dynes s cm^{-5}, p <0.01) than in patients with normal LV stress. Decreased LV stress was caused by decreased systolic and diastolic pressures and/or volumes. Late systolic pressure-volume relations in patients with normal LV stress suggested increased myocardial contractility, but this was not confirmed by LV dP/dt. Hydralazine improves LV function in patients with dilated cardiomyopathy by reducing elevated LV wall stress, with little inotropic effect.

(Am J Cardiol 1985;56:690–695)

Although hydralazine administration increases stroke volume in patients with chronic congestive heart failure, the mechanism of this response is not well established. Patients differ in responsiveness to vasodilators, which has been related to differences in systemic vascular resistance, left ventricular end-diastolic pressure (LVEDP), and LV cavity size.[1,2] The association of LV dilation with a good response to hydralazine suggests that vasodilators may act through a reduction in LV wall stress.[2–6] The positive inotropic effect of hydralazine may also play a role.[7] To assess the role of LV stress and inotropy in hydralazine therapy, we examined the effect of intravenous hydralazine on LV pressure-volume and stress-volume relations, vascular resistance, and indexes of cardiac performance in 9 patients with idiopathic dilated cardiomyopathy.

Methods

Patients: Nine patients were studied during cardiac catheterization after optimal diuresis without vasodilator therapy, often requiring both furosemide (as much as 800 mg/day) and metolazone (as much as 10 mg/day). No complications resulted from this study.

Hydralazine administration: Hydralazine was administered intravenously in sequential 5-mg doses every 5 minutes, titrated to decrease arteriovenous oxygen saturation difference to about half baseline values, approximately doubling cardiac output. The mean total dose was 27 mg (range 10 to 60).

Catheterization: Biplane left ventriculography with simultaneous LV micromanometry (Millar Instruments), dP/dt and right atrial pressure recordings were performed before and after hydralazine administration. Central aortic micromanometer pressure was recorded immediately before each ventriculogram. Contrast-induced pressure shifts during ventriculography[8,9] were avoided either by using 2 catheters or by using a custom-guiding catheter that allowed intraventricular micromanometer placement during injection. At least 30 minutes elapsed between ventriculograms taken before and after administration of hydralazine to allow contrast effects to dissipate.[8,9] Coronary arteriography showed no significant coronary artery disease.

Data calculation: Biplane LV images were digitized frame by frame (60 frames/s) over 2 successive cardiac cycles both before and after hydralazine administration. LV perimeters were corrected for pincushion distortion and tube-to-screen magnification by a biplane triangulation technique.[10] LV volume was calculated by the biplane area-length method.[11]

* $p \leq 0.01$; † $p < 0.05$ vs control or vs high stress group, defined by analysis of variance.
ArtP = arterial pressure (systemic); C = control; CHF = congestive heart failure; D = diastolic; EDP = end-diastolic pressure; EDVI = end-diastolic volume index; EF = ejection fraction; H = hydralazine; HR = heart rate; LVP = left ventricular pressure; S = systolic; SVI = stroke volume index; SVR = systemic vascular resistance.

LV mass was calculated from radiographic end-diastolic wall thickness.[12] Wall thickness was calculated for each frame by an iteration technique using the first mass.[13] Circumferential wall stress was calculated from the formula for a thin-walled prolate spheroid.[14] LV wall stress and systemic vascular resistance were considered high when they exceeded 450 kdynes/cm^2 and 1,500 dyne s cm^{-5}, respectively.[15,16]

Central aortic pressure was superimposed on LV pressure to determine the time of aortic valve closure, which was used to determine end-systolic pressure and wall stress. The smallest LV volume determined end-systolic volume. Peak dP/dt was taken from the analog derivative of the pressure tracing.[17]

Statistical methods: Ventriculographic data were smoothed using a 9-point polynomial approximation technique. Values presented are the average of the 2 consecutive beats. The significance of differences was defined by analysis of variance.

Accuracy and reproducibility: Immediately before each ventriculogram, micromanometer pressure traces were superimposed on simultaneous LV pressure traces from mercury-calibrated air-reference transducers. The accuracy of pressures is therefore within 5 mm Hg. Our computerized x-ray dimension system[10] can measure distances between beads randomly oriented in the x-ray field with 95% confidence limits (±2 standard deviations) of ±1 mm, and can measure the volume of human LV latex casts with 95% confidence limits of ±15 ml, which is less than 5% of most LV volumes in these patients.

Results

Table I is a summary of clinical characteristics and hemodynamic values in the 8 patients during control conditions and after hydralazine administration. Patients 1 to 8 are arranged in order of decreasing peak LV

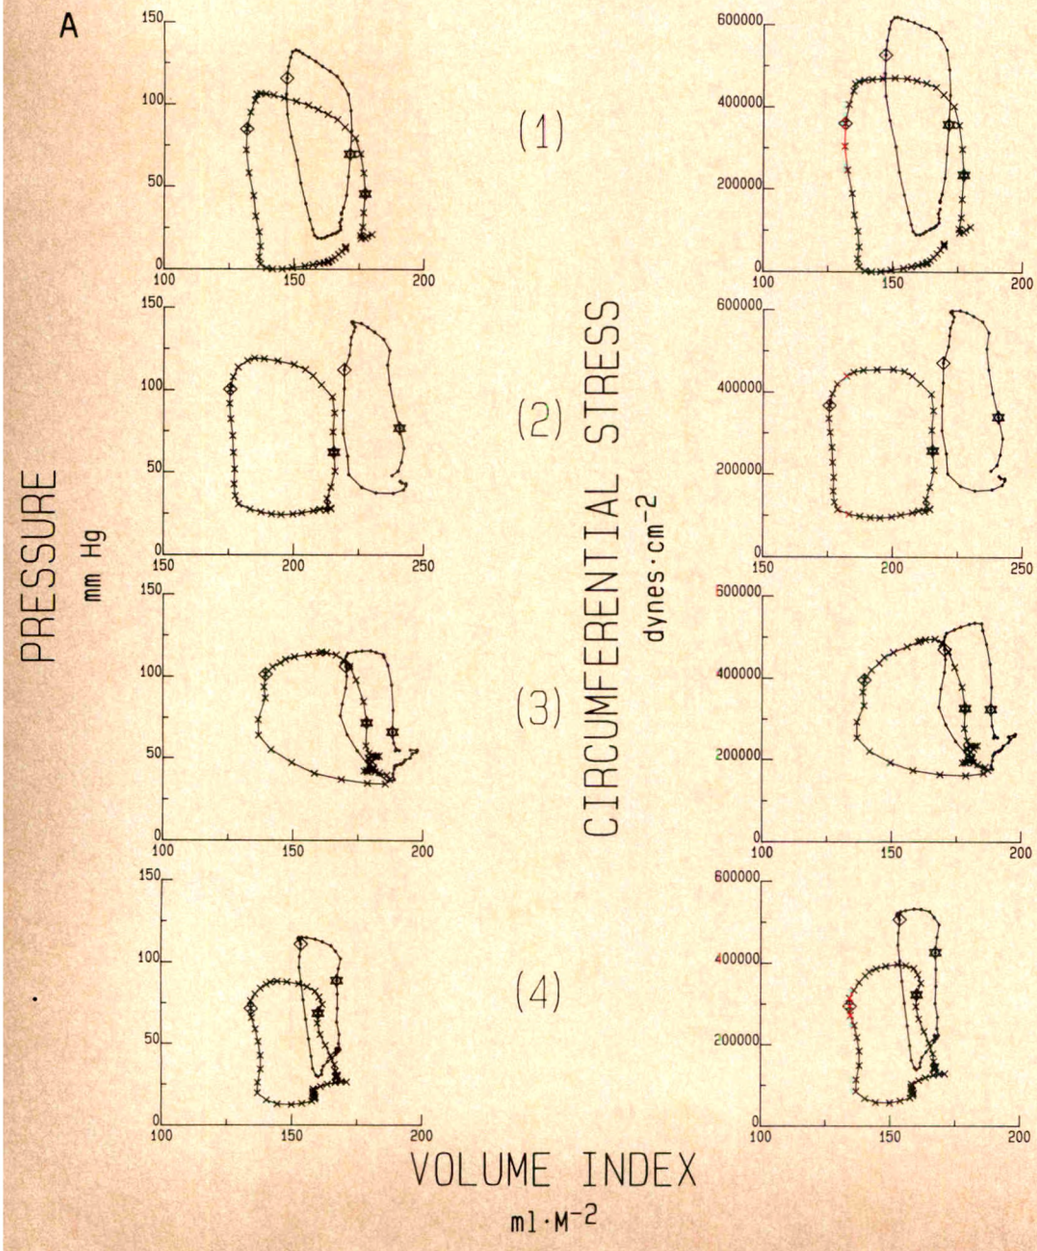

FIGURE 1. A and **B**, pressure-volume (**left**) and stress-volume (**right**) loops in patients before (**dots**) and after (**x**) hydralazine infusion. **Stars** mark aortic valve opening and **diamonds** mark aortic valve closure. Patient 2's value is plotted on a larger volume axis than the others. In patients 1 (**A**) to 5 (**B** on opposite page), who have higher pretreatment wall stress and greater ventricular dilation, hydralazine caused prominent diastolic effects not seen in patients with lower pretreatment wall stress and less ventricular dilation (nos. 6 to 8, opposite page). In the latter patients, end-systolic volume decreased whether or not end-systolic pressure and stress decreased.

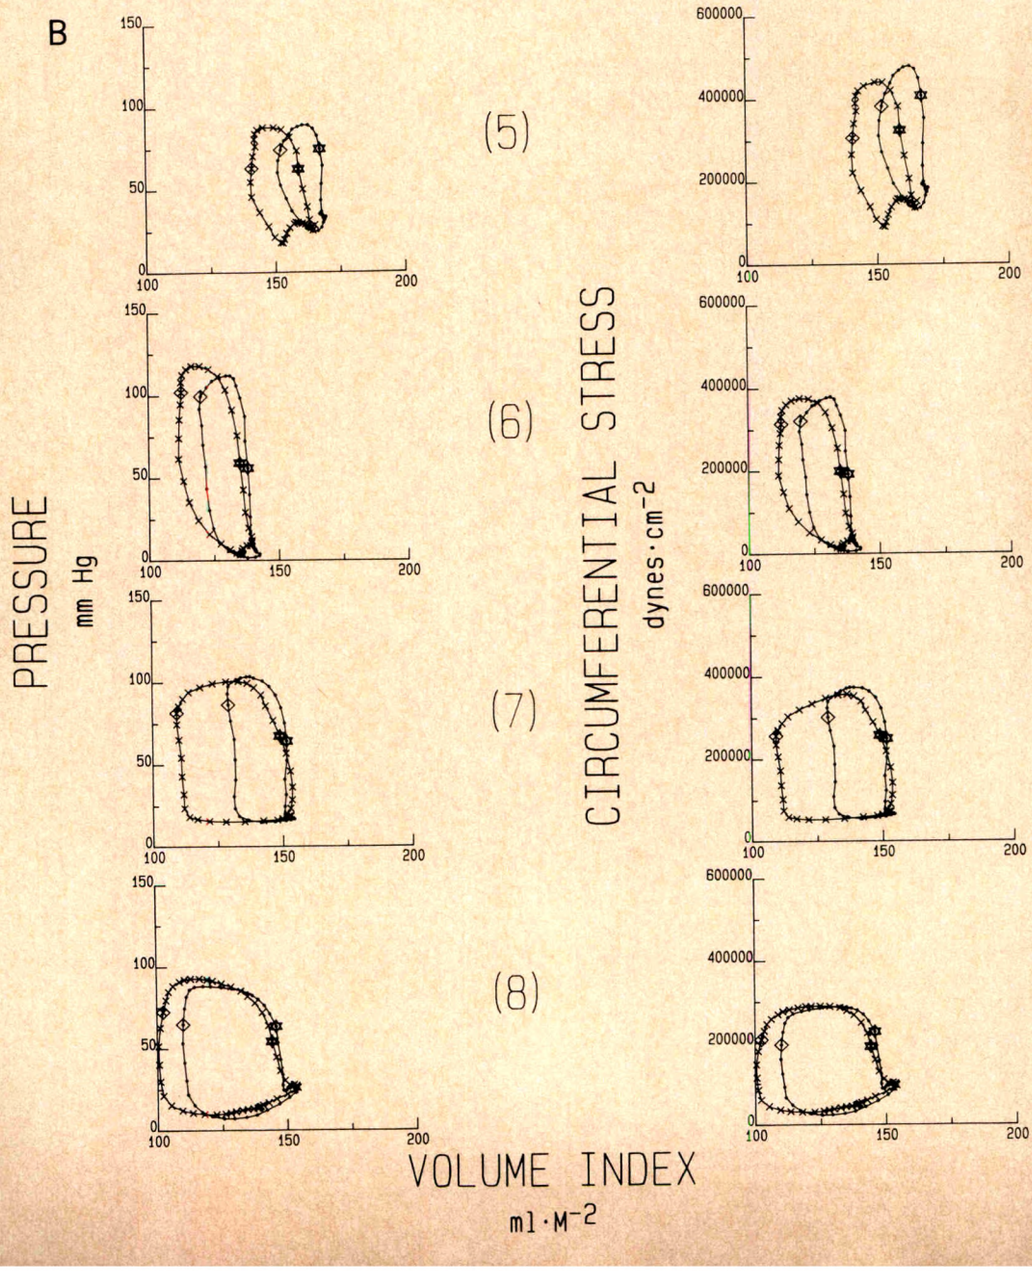
wall stress values. Patients 1 to 5 had high baseline peak wall stress, whereas patients 6 to 8 had normal baseline peak wall stress.

In the 8 patients as a group, stroke volume index and ejection fraction increased significantly after hydralazine and systemic vascular resistance and wall stress decreased. There were no changes in LV pressure, arterial pressure, end-diastolic volume index or peak dP/dt.

Patients with high peak LV wall stress differed from those with normal peak wall stress in several ways. LVEDP, arterial diastolic pressure, end-diastolic volume index and systemic vascular resistance were significantly higher in the 5 patients with high peak LV wall stress, while ejection fraction was lower. Systolic arterial and LV pressures, stroke volume and peak dP/dt were no different between patients with high and those with normal peak wall stress. The groups formed on the basis of normal or high peak wall stress are nearly the same as would be formed by separation of normal from high systemic vascular resistance or LVEDP.

Changes during hydralazine therapy also differed between patients with normal and those with high peak stress. LV and arterial diastolic and systolic pressures, LV stress and systemic vascular resistance all decreased more in patients with high peak stress. The increase in stroke volume was numerically greater in patients with high peak stress, but this difference was not significant in these 8 patients.

Pressure-volume and stress-volume points are plotted in Figure 1. Patient 2, whose heart was the most dilated, is plotted on a larger volume axis than the others. As shown in Table I, patients 1 to 5 had higher peak wall stress and more LV dilation than patients 6 to 8. Hy-



dralazine lowered LV pressure and/or diastolic volume in patients 1 to 5, but did not in patients 6 to 8. Peak systolic pressure decreased substantially in patients 1, 2 and 4 in whom hydralazine also decreased LVEDP. In patients 2, 3 and 5, LV diastolic volume decreased. In these patients, decreased diastolic volume persisted through early systole, contributing to decreased systolic volume (note displacement of right sides of loops to lower volume). Thus, both decreased LV pressure and volume decreased wall stress in patients 1 to 5. In contrast, hydralazine did not change systolic pressure or diastolic pressure-volume relations in patients 6 to 8, so that end-systolic wall stress did not decrease.

Discussion

During hydralazine therapy for idiopathic dilated cardiomyopathy, increased stroke volume resulted from decreased end-systolic volume, accompanied by decreased LV wall stress and decreased systemic resistance. Arterial and LV pressure were not significantly decreased. Our patients could be classified into 2 groups on the basis of normal or high LV stress. Patients with high LV stress had hemodynamically more severe heart failure with higher diastolic arterial pressure and LVEDP, higher LV volume, higher systemic resistance and lower stroke volume and ejection fraction than patients with normal LV stress. The severity of heart failure was not a function of patient age or of duration of symptoms.

Our findings support the conclusions of other investigators who have tried to predict the response to vasodilators in heart failure by hemodynamic stratification. Patients with higher systemic resistance or higher LVEDP respond better to vasodilators.[1] Hydralazine increases stroke volume more in patients with larger LV dimensions.[2] Although stroke volume did not increase more in our patients who had higher systemic resistance, larger LV cavities, higher LVEDP and high LV wall stress than in patients with normal wall stress, the trend toward higher stroke volume in the high stress group might have been significant with more patients.[1,2] Hydralazine decreased wall stress, LV pressure and systemic resistance more in patients with high LV wall stress than in those with normal LV stress.

Although previous workers have speculated that responsiveness to hydralazine is a function of pretreatment LV wall stress,[2] none have studied changes in wall stress, pressure-volume relations and stress-volume relations during vasodilator therapy. Our findings support the hypothesis that patients with high pretreatment LV stress respond better to vasodilators.[2] Additionally, changes in pressure- and stress-volume relations in our study explain the association between high wall stress and better response to hydralazine.[2] Vasodilator "unloading" in congestive heart failure probably acts by reducing systolic wall stress against which the failing left ventricle ejects.[3–5] In patients with high LV wall stress (loops 1 to 5), hydralazine reduces pressures (arterial pressure, LV systolic pressure and LVEDP) (loops 1, 2 and 4) or reduces end-diastolic volume (loops 2, 3 and 5). Reduced LV end-diastolic volume after hydralazine "carries through" to systole as shown by leftward displacement of the right and top portions of loops 2, 3 and 5. Because wall stress is directly proportional to LV pressure and volume (through changes in LV radius and wall thickness), either decreased LV systolic pressure or volume decreases end-systolic LV stress.[14,18] Hydralazine did not decrease LV systolic pressure and LV diastolic volume in patients with normal pretreatment LV stress (loops 6 to 8). Thus, hydralazine decreases end-systolic wall stress in patients with high pretreatment LV stress, unloading the left ventricle by effects on both ventricular pressure and volume.

Our data are not entirely consistent with the hypothesis that hydralazine increases LV stroke volume by reducing LV stress. End-systolic stress did not always decrease despite decreased end-systolic volume (loops 6 and 8). Hydalazine may also increase LV stroke volume by a direct inotropic effect. Hydralazine increases LV contractility in nonfailing ventricles.[7] In patients 6 and 8, hydralazine shifted late systolic pressure-volume relations (upper left corners of loops) toward higher pressure or wall stress despite lower volume, consistent with increased LV contractility.[4,5,19] Another index of cardiac performance, peak positive LV dP/dt, reflects changes in LV contractility in the absence of changes in LVEDP.[20–23] Although shifts in systolic pressure-volume relations in our patients suggested increased LV contractility, changes in peak LV dP/dt did not. This discrepancy may indicate relative insensitivity of LV dP/dt to changes in contractility. Alternatively, changes in late systolic pressure-volume relations may be dependent on systemic resistance, a concept that is both supported and refuted by experimental data.[24–26] Although inotropy may play a role in determining responsiveness to hydralazine in congestive heart failure, this role is probably relatively unimportant.

We conclude that hydralazine improves LV function in patients with cardiomyopathy by reducing elevated LV wall stress through reduced LV pressure and volume. Hydralazine has little inotropic effect in these patients. Further studies may establish the efficacy of hemodynamic stratification in selecting candidates for vasodilator therapy.

ROCHE®

OVERLOAD

Reduce fluid volume and improve hemodynamics in CHF

Edema due to congestive heart failure often demands highly effective diuresis to reduce the fluid load on the failing heart. Bumex® (bumetanide/Roche) is the next generation in loop diuretic therapy for three powerful reasons. It moves out an unsurpassed volume of fluid and sodium, resulting in significant reductions in edema and right atrial and pulmonary artery wedge pressures.[1,2] It's almost completely absorbed through the GI tract, so it's easy to titrate.[3] And Bumex completes high-volume diuresis fast—within four hours at usual doses.[4,5] Your patients spend less time in diuresis, more time in normal activities.

Bumex has a good safety profile; however, as with all loop diuretics, Bumex, if given in excessive amounts, can lead to profound diuresis with water and electrolyte depletion, including hypokalemia. Serum electrolytes should be monitored periodically, especially in patients on low salt diets or those treated for prolonged periods or on high doses.

Bumex®
bumetanide/Roche
0.5-mg and 1-mg scored tablets/2-ml ampuls, 2-ml, 4-ml and 10-ml vials (0.25 mg/ml)

The next generation in loop diuretic therapy

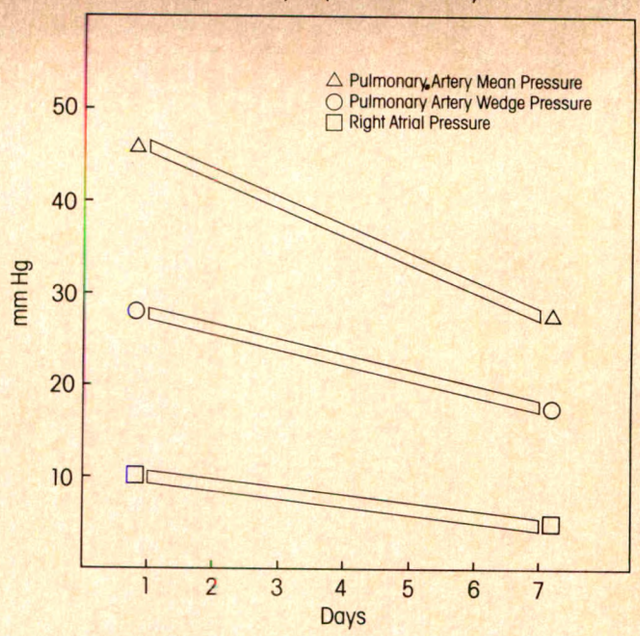
Bumex®

bumetanide/Roche

0.5-mg and 1-mg scored tablets/2-ml ampuls, 2-ml, 4-ml and 10-ml vials (0.25 mg/ml)

REDUCES FLUID OVERLOAD and eases the burden on the failing heart

Significantly improves hemodynamics



Ten patients with CHF showed marked hemodynamic improvement after seven days of BUMEX* (bumetanide/Roche) (mean values ± SE). Adapted from Olesen, *et al.*[1]

BUMEX®
bumetanide/Roche
0.5-mg and 1-mg scored tablets
2-ml ampuls, 2-ml, 4-ml and
10-ml vials (0.25 mg/ml)

BUMEX® (bumetanide/Roche)
Before prescribing, please consult complete product information, a summary of which follows:

WARNING: Bumex (bumetanide/Roche) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dosage schedule have to be adjusted to the individual patient's needs. (See under DOSAGE AND ADMINISTRATION in complete product information.)

INDICATIONS AND USAGE: Edema associated with congestive heart failure, hepatic and renal disease, including the nephrotic syndrome.
Almost equal diuretic response occurs after oral and parenteral administration of Bumex.
If impaired gastrointestinal absorption is suspected or oral administration is not practical, Bumex should be given by the intramuscular or intravenous route.
Successful treatment with Bumex following instances of allergic reactions to furosemide suggests a lack of cross-sensitivity.
CONTRAINDICATIONS: Anuria. Hypersensitivity and in patients in hepatic coma or in states of severe electrolyte depletion. Although Bumex can be used to induce diuresis in renal insufficiency, any marked increase in blood urea nitrogen or creatinine, or the development of oliguria during therapy of patients with progressive renal disease, is an indication for discontinuation of treatment.
WARNINGS: Dose should be adjusted to patient's needs. Excessive doses or too frequent administration can lead to profound water loss, electrolyte depletion, dehydration, reduction in blood volume and circulatory collapse with the possibility of vascular thrombosis and embolism, particularly in elderly patients.
Prevention of hypokalemia requires particular attention in patients receiving digitalis and diuretics for congestive heart failure, hepatic cirrhosis and ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, certain diarrheal states, or other states where hypokalemia is thought to represent particular added risks to the patients.
In patients with hepatic cirrhosis and ascites, sudden alterations of electrolyte balance may precipitate hepatic encephalopathy and coma. Treatment in such patients is best initiated in the hospital with small doses and careful monitoring of the patient's clinical status and electrolyte balance. Supplemental potassium and/or spironolactone may prevent hypokalemia and metabolic alkalosis in these patients.
In cats, dogs and guinea pigs, Bumex has been shown to produce ototoxicity. Since Bumex is about 40 to 60 times as potent as furosemide, it is anticipated that blood levels necessary to produce ototoxicity will rarely be achieved. The potential for ototoxicity increases with intravenous therapy, especially at high doses.
Patients allergic to sulfonamides may show hypersensitivity to Bumex.
PRECAUTIONS: Measure serum potassium periodically and add potassium supplements or potassium-sparing diuretics, if necessary. Periodic determinations of other electrolytes are advised in patients treated with high doses or for prolonged periods, particularly in those on low salt diets.
Hyperuricemia may occur. Reversible elevations of the BUN and creatinine may occur, especially with dehydration and in patients with renal insufficiency. Bumex may increase urinary calcium excretion.
Possibility of effect on glucose metabolism exists. Periodic determinations of blood sugar should be done, particularly in patients with diabetes or suspected latent diabetes.
Patients should be observed regularly for possible occurrence of blood dyscrasias, liver damage or idiosyncratic reactions.
Especially in presence of impaired renal function, use of parenterally administered Bumex should be avoided in patients to whom aminoglycoside antibiotics are also being given, except in life-threatening conditions.
Drugs with nephrotoxic potential and bumetanide should not be administered simultaneously.
Since lithium reduces renal clearance and adds a high risk of lithium toxicity, it should not be given with diuretics.
Probenecid should not be administered concurrently with Bumex.
Concurrent therapy with indomethacin not recommended.
Bumex may potentiate the effects of antihypertensive drugs, necessitating reduction in dosage.
Interaction studies in humans have shown no effect on digoxin blood levels.
Interaction studies in humans have shown Bumex to have no effect on warfarin metabolism or on plasma prothrombin activity.
Pregnancy: Bumex should be given to a pregnant woman only if the potential benefit justifies the potential risk to the fetus.
Bumetanide may be excreted in breast milk.
Pediatric Use: Safety and effectiveness below age 18 not established.
ADVERSE REACTIONS: Muscle cramps, dizziness, hypotension, headache and nausea, and encephalopathy (in patients with preexisting liver disease).
Less frequent clinical adverse reactions are weakness, impaired hearing, rash, pruritus, hives, electrocardiogram changes, abdominal pain, arthritic pain, musculoskeletal pain and vomiting.
Other clinical adverse reactions are vertigo, chest pain, ear discomfort, fatigue, dehydration, sweating, hyperventilation, dry mouth, upset stomach, renal failure, asterixis, itching, nipple tenderness, diarrhea, premature ejaculation and difficulty maintaining an erection.
Laboratory abnormalities reported are hyperuricemia, azotemia, hyperglycemia, increased serum creatinine, hypochloremia, hypokalemia, hyponatremia, and variations in CO_2 content, bicarbonate, phosphorus and calcium. Although manifestations of the pharmacologic action of Bumex, these conditions may become more pronounced by intensive therapy.
Diuresis induced by Bumex may also rarely be accompanied by changes in LDH, total serum bilirubin, serum proteins, SGOT, SGPT, alkaline phosphatase, cholesterol, creatinine clearance, deviations in hemoglobin, prothrombin time, hematocrit, platelet counts and differential counts. Increases in urinary glucose and urinary protein have also been seen.
DOSAGE AND ADMINISTRATION:
Oral Administration: The usual total daily dosage is 0.5 to 2.0 mg and in most patients is given as a single dose.
Parenteral Administration: Administer to patients (IV or IM) with GI absorption problem or who cannot take oral. The usual initial dose is 0.5 to 1 mg given over 1 to 2 minutes. If insufficient response, a second or third dose may be given at 2 to 3 hour intervals up to a maximum of 10 mg a day.
HOW SUPPLIED: *Tablets*, 0.5 mg (light green) and 1 mg (yellow), bottles of 100 and 500; Prescription Paks of 30; Tel-E-Dose® cartons of 100. Imprint on tablets: 0.5 mg—ROCHE BUMEX 0.5; 1 mg—ROCHE BUMEX 1.
Ampuls, 2 ml, 0.25 mg/ml, boxes of ten.
Vials, 2 ml, 4 ml and 10 ml, 0.25 mg/ml, boxes of ten.

Introducing Liteguard 9...

The most technically advanced, *COST EFFECTIVE* defibrillator ever!

FOUR devices in **ONE** lightweight, portable package.

ECG Monitor

- Large 5″, easy to read screen with freeze mode
- Digital heart rate (on screen) 20–250 bpm
- Adjustable heart rate alarms with auto write-out
- QRS beeper with volume control
- Dual opto-isolated preamplifiers for patient safety

ECG Recorder

- Diagnostic 12 lead capability
- Diagnostic bandwidth .05–100 HZ
- Real time or delayed recording
- Annotated recording prints date, time, lead, gain, heart rate, delay, energy selected, and transthoracic resistance

Defibrillator

- 5–360 joules and synchronizer capability
- External, internal, and pediatric paddles
- Microprocessor based design with sealed membrane keyboard
- Liquid crystal display keeps operator informed of all selections and instrument status
- Versatile, multiple battery and A.C. operation

Defibrillator Tester

- Digital display of actual delivered energy in joules
- Automatic self-diagnosis of all switches, memory and program on startup

The Liteguard 9 also features TTR (Transthoracic Resistance Measurement)

Patient's transthoracic resistance is measured to ensure good paddle contact and to assist the operator in energy selection as a means of possibly reducing myocardial damage caused by defibrillation.

The Liteguard 9 is the newest member of Survival's growing family of the world's smallest and most cost effective defibrillators.

For more information or a demonstration, contact:

Survival Technology Inc.

8101 Glenbrook Road, Bethesda, MD 20814
800-638-8093 (in MD 301-656-5600)

Liteguard is manufactured by TemTech Ltd.

A SYMPOSIUM...

THE ROLE OF CALCIUM CHANNEL BLOCKERS IN THE MANAGEMENT OF HYPERTENSION

Sunday, November 10, 1985
Cotillion Ballroom South
Sheraton Washington Hotel
2660 Woodley Road NW
Washington, DC
9:00 AM-12:00 PM: Symposium

Sponsored by
The Alton Ochsner Medical Foundation

For reservations, please call toll free: 1-800-443-0100, ext. 477

A buffet breakfast will be held prior to the Symposium at 8:00 AM in the Cotillion Ballroom North, and a luncheon reception will follow the Symposium at 12:15 PM in the Cotillion Ballroom North.

Moderator
Aram V. Chobanian, MD
Symposium Chairman and Moderator
Professor of Medicine
Director, Cardiovascular Institute
Boston University School of Medicine
Boston, MA

Pharmacology of Calcium Channel Blockers

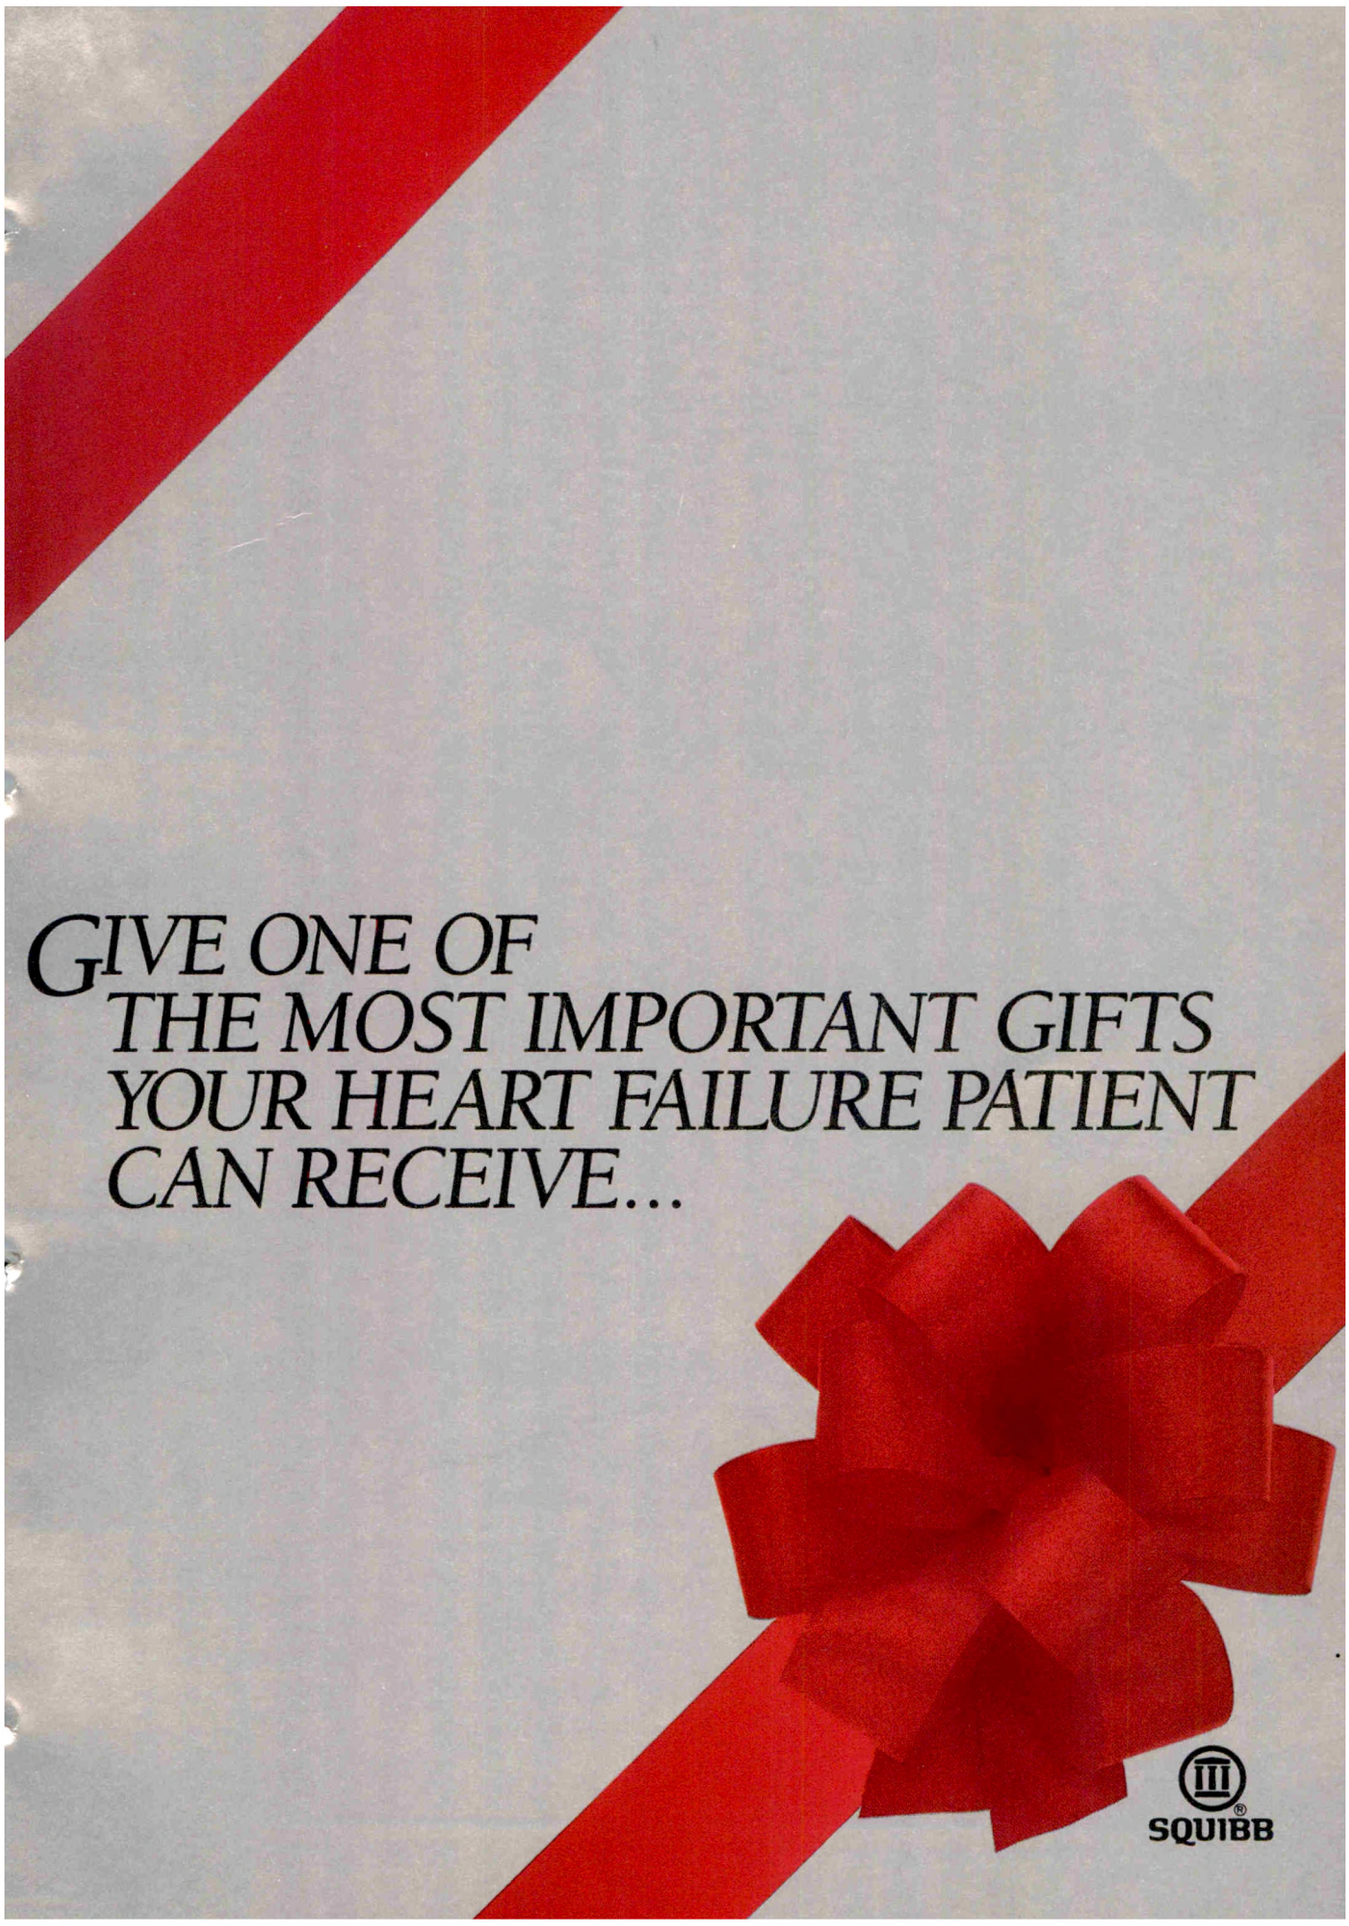
Cape Town, South Africa

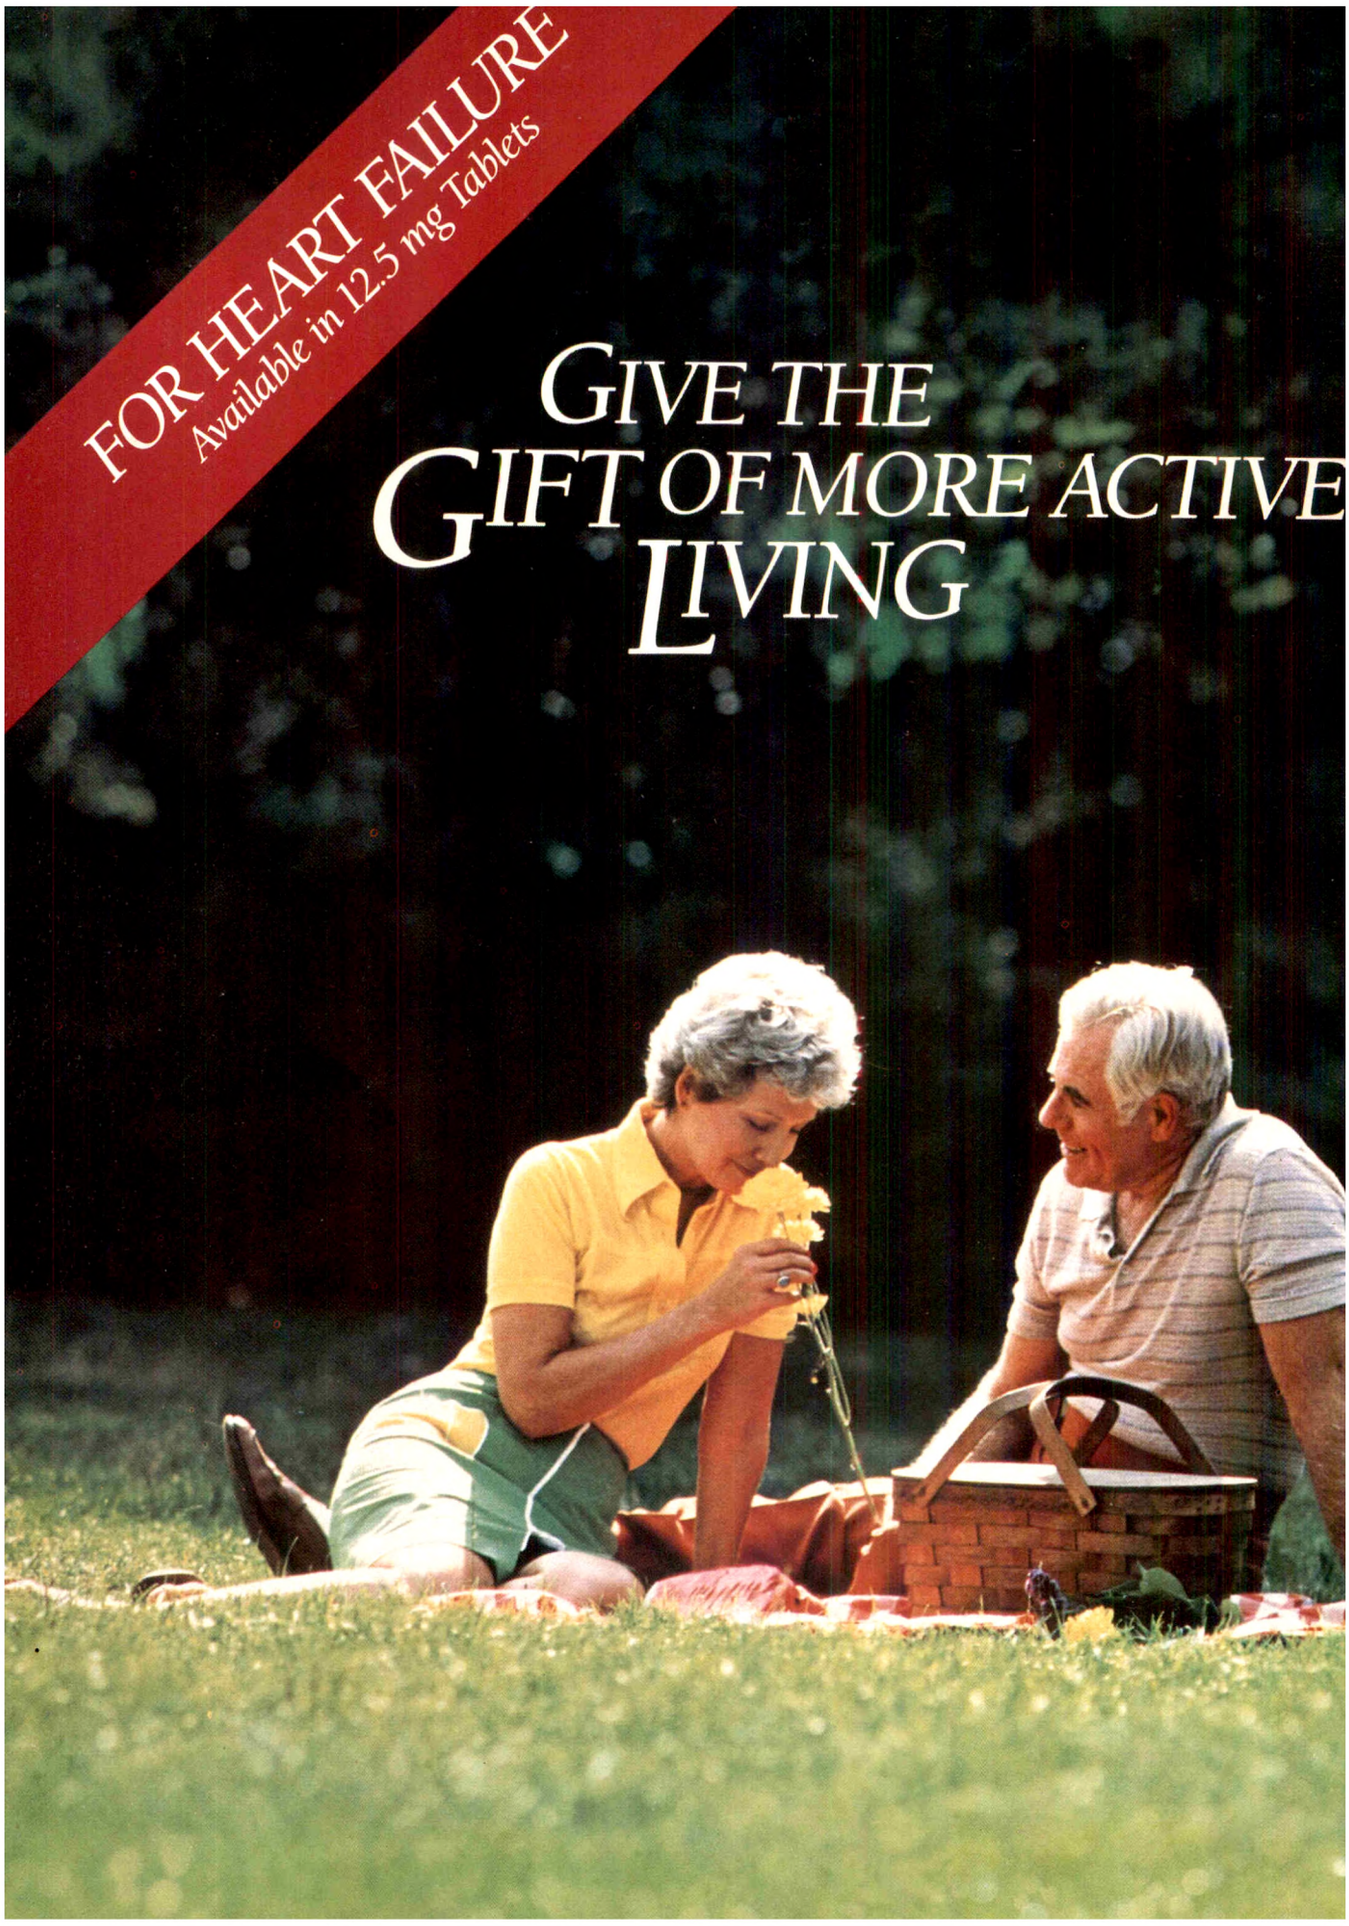
As an organization accredited for Continuing Medical Education, The Alton Ochsner Medical Foundation certifies that this Continuing Medical Education Program meets the criteria for three (3) credit hours in Category I of the Physician's Recognition Award of the American Medical Association.

This Symposium is supported by an educational grant provided by Pfizer Laboratories. © 1985, Pfizer Inc.

GIVE ONE OF THE MOST IMPORTANT GIFTS YOUR HEART FAILURE PATIENT CAN RECEIVE...



SQUIBB®



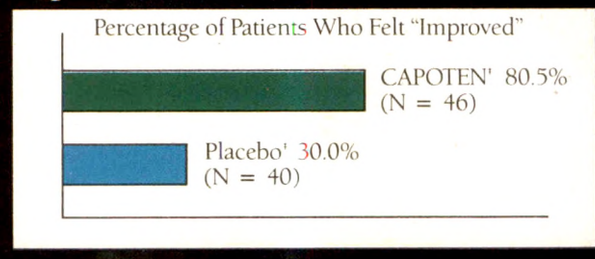
FOR HEART FAILURE
Available in 12.5 mg Tablets
GIVE THE
GIFT OF MORE ACTIVE
LIVING

CAPOTEN ENHANCES PATIENTS' QUALITY OF LIFE

□ **Relieves symptoms.**
Significantly greater improvement in dyspnea, fatigue, orthopnea, and edema with CAPOTEN than with digitalis and diuretics alone.†[1]

□ **Increases ability to exercise.**
A 24.3% increase after 12 weeks of CAPOTEN versus 0.4% with digitalis and diuretics alone.†[1]

8 out of 10 Patients Rated Themselves "Improved" with CAPOTEN[1]



□ *Use CAPOTEN when symptoms persist despite digitalis and diuretic therapy.*

ACE*INHIBITOR

CAPOTEN® (captopril tablets) IN HEART FAILURE§

YOUR FIRST CHOICE AFTER DIGITALIS AND DIURETICS

*Angiotensin Converting Enzyme

†Ninety-two patients, refractory to but continuing on digitalis and diuretics, were given CAPOTEN or placebo for 12 weeks. Patients were primarily New York Heart Association Class II and Class III. Dosages of CAPOTEN ranged from an initial 25 mg tid to a maximum maintenance dosage of 100 mg tid.[1]

‡Given with digitalis and diuretics.

§CAPOTEN is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis. In using CAPOTEN, consideration should be given to the risk of neutropenia/agranulocytosis. Use special precautions in patients with impaired renal function, collagen vascular disorders, or those exposed to other drugs (e.g., procainamide) known to affect the white cells or immune response. Evaluation of heart failure patients should always include assessment of renal function. See INDICATIONS, WARNINGS, and ADVERSE REACTIONS in the brief summary on the adjacent page.

INDICATIONS: Hypertension – CAPOTEN (captopril) is indicated for the treatment of hypertension. Consideration should be given to the risk of neutropenia/agranulocytosis (see WARNINGS). CAPOTEN may be used as initial therapy for patients with normal renal function, in whom the risk is relatively low. In patients with impaired renal function, particularly those with collagen vascular disease, captopril should be reserved for those who have either developed unacceptable side effects on other drugs, or have failed to respond satisfactorily to drug combinations. CAPOTEN is effective alone and in combination with other antihypertensive agents, especially thiazide-type diuretics.

Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

WARNINGS: Neutropenia/Agranulocytosis – Neutropenia (<1000/mm³) with myeloid hypoplasia has resulted from use of captopril. About half of the neutropenic patients developed systemic or oral cavity infections or other features of the syndrome of agranulocytosis. The risk of neutropenia is dependent on the clinical status of the patient:

In clinical trials in patients with hypertension who have normal renal function (serum creatinine <1.6 mg/dL and no collagen disease), neutropenia has been seen in one patient out of over 8,600 exposed. In patients with some degree of renal failure (serum creatinine at least 1.6 mg/dL) but no collagen vascular disease, the risk in clinical trials was about 1 per 500. Doses were relatively high in these patients, particularly in view of their diminished renal function. In patients with collagen vascular diseases (e.g., systemic lupus erythematosus, scleroderma) and impaired renal function, neutropenia occurred in 3.7% of patients in clinical trials. While none of the over 750 patients in formal clinical trials of heart failure developed neutropenia, it has occurred during subsequent clinical experience. Of reported cases, about half had serum creatinine ≥1.6 mg/dL and more than 75% received procainamide. In heart failure, it appears that the same risk factors for neutropenia are present.

Neutropenia has appeared within 3 months after starting therapy, associated with myeloid hypoplasia and frequently accompanied by erythroid hypoplasia and decreased numbers of megakaryocytes (e.g., hypoplastic bone marrow and pancytopenia); anemia and thrombocytopenia were sometimes seen. Neutrophils generally returned to normal in about 2 weeks after captopril was discontinued, and serious infections were limited to clinically complex patients. About 13% of the cases of neutropenia have ended fatally, but almost all fatalities were in patients with serious illness, having collagen vascular disease, renal failure, heart failure or immunosuppressant therapy, or a combination of these complicating factors.

Evaluation of the hypertensive or heart failure patient should always include assessment of renal function. If captopril is used in patients with impaired renal function, white blood cell and differential counts should be evaluated prior to starting treatment and at approximately 2-week intervals for about 3 months, then periodically. In patients with collagen vascular disease or who are exposed to other drugs known to affect the white cells or immune response, particularly when there is impaired renal function, captopril should be used only after an assessment of benefit and risk, and then with caution. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat, fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.

Proteinuria – Total urinary proteins >1 g/day were seen in about 0.7% of patients on captopril. About 90% of affected patients had evidence of prior renal disease or received high doses (>150 mg/day), or both. The nephrotic syndrome occurred in about one-fifth of proteinuric patients. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients. Since most cases of proteinuria occurred by the 8th month of therapy, patients with prior renal disease or those receiving captopril at doses >150 mg/day should have urinary protein estimates (dip-stick on 1st morning urine) before therapy, and periodically thereafter.

Hypotension – Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]).

In heart failure, where blood pressure was either normal or low, transient decreases in mean blood pressure >20% were recorded in about half of the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

PRECAUTIONS: General: *Impaired Renal Function,* Hypertension – Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure – About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* – A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis due to decreased afterload reduction.

Surgery/Anesthesia – If hypotension occurs during major surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.

tion of blood pressure may occasionally occur within the 1st hour after administrat of the initial captopril dose in patients on diuretics, especially those recently placed diuretics, and those on severe dietary salt restriction or dialysis. This possibility be minimized by either discontinuing the diuretic or increasing the salt intake ab 1 week prior to initiation of captopril therapy or by initiating therapy with sm doses (6.25 or 12.5 mg). Alternatively, provide medical supervision for at least 1 h after the initial dose.

Agents Having Vasodilator Activity – In heart failure patients, vasodilators sho be administered with caution.

Agents Causing Renin Release – Captopril's effect will be augmented by antihyperten agents that cause renin release.

Agents Affecting Sympathetic Activity – The sympathetic nervous system may especially important in supporting blood pressure in patients receiving captoj alone or with diuretics. Beta-adrenergic blocking drugs add some further antihyperten effect to captopril, but the overall response is less than additive. Therefore, use age affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neu blocking agents) with caution.

Agents Increasing Serum Potassium – Give potassium-sparing diuretics or potassi supplements only for documented hypokalemia, and then with caution, since th may lead to a significant increase of serum potassium. Use potassium-containing s substitutes with caution.

Inhibitors of Endogenous Prostaglandin Synthesis – Indomethacin and other nonsteroi anti-inflammatory agents may reduce the antihypertensive effect of captopril, esp cially in low renin hypertension.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive ur test for acetone.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Two-year stud with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Pregnancy: Category C – There are no adequate and well-controlled studies pregnant women. Embryocidal effects were observed in rabbits. Therefore, captoj should be used during pregnancy only if the potential benefit outweighs the potent risk to the fetus. Captopril crosses the human placenta.

Nursing Mothers: Captopril is secreted in human milk. Exercise caution when a ministering captopril to a nursing woman, and, in general, nursing should be interrupt

Pediatric Use: Safety and effectiveness in children have not been establish although there is limited experience with use of captopril in children from 2 mont to 15 years of age. Dosage, on a weight basis, was comparable to that used in adul Captopril should be used in children only if other measures for controlling blo pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials invo ing approximately 7000 patients.

Renal – About 1 of 100 patients developed proteinuria (see WARNINGS). Renal sufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patie

Hematologic – Neutropenia/agranulocytosis have occurred (see WARNINGS). An mia, thrombocytopenia, and pancytopenia have been reported.

Dermatologic – Rash (usually maculopapular, rarely urticarial), often with prurit and sometimes with fever and eosinophilia, in about 4 to 7 of 100 patients (dependi on renal status and dose), usually during the 1st 4 weeks of therapy. Pruritus, withc rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, a photosensitivity have also been reported. Angioedema of the face, mucous mei branes of the mouth, or of the extremities in about 1 of 1000 patients – reversible discontinuance of captopril therapy. One case of laryngeal edema reported. Flushi or pallor in 2 to 5 of 1000 patients.

Cardiovascular – Hypotension may occur, see WARNINGS and PRECAUTION (Drug Interactions) for discussion of hypotension on initiation of captopril thera Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angi pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failu each in 2 to 3 of 1000 patients.

Dysgeusia – About 2 to 4 (depending on renal status and dose) of 100 patie developed a diminution or loss of taste perception; taste impairment is reversible a usually self-limited even with continued drug use (2 to 3 months). Gastric irritatic abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulce peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspn cough, alopecia, and paresthesias reported in about 0.5 to 2% of patients but did appear at increased frequency compared to placebo or other treatments used controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patie although no causal relationship has been established. Rarely cholestatic jaundice a hepatocellular injury with or without secondary cholestasis, have been reported. transient elevation of BUN and serum creatinine may occur, especially in volum depleted or renovascular hypertensive patients. In instances of rapid reduction longstanding or severely elevated blood pressure, the glomerular filtration rate m decrease transiently, also resulting in transient rises in serum creatinine and BU Small increases in serum potassium concentration frequently occur, especially patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern is correction of hypotension. Volume expansi with an I.V. infusion of normal saline is the treatment of choice for restoration blood pressure. Captopril may be removed from the general circulation by hemodialys

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be tak one hour before meals. In hypertension, CAPOTEN may be dosed bid or tid. Dosa must be individualized; see DOSAGE AND ADMINISTRATION section of pac age insert for detailed information regarding dosage in hypertension and in hea failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosa adjustments are recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of 12.5, 25, 50, and 100 mg in bottles of 1 (25 mg also available in bottles of 1000), and in UNIMATIC® single dose packs of 1 tablets.
(J3-658C)

Left Ventricular Apical Masses: Noninvasive Differentiation of Rare from Common Ones

ANDRE KEREN, MD
TOSHIHIKO TAKAMOTO, MD
DONALD C. HARRISON, MD
RICHARD L. POPP, MD

Previous investigators[1–3] have described 2-dimensional echocardiographic (2-D echo) features of uncommon cardiac masses. The value of 2-D echo criteria in distinguishing these masses from thrombi has not been analyzed systematically. We designed this study to assess the usefulness and limitations of clinical and 2-D echo criteria in differentiating among distinct types of LV apical masses.

A search of our data bank for patients in whom good quality 2-D echocardiograms showing obvious masses involving the LV apical area yielded 3 patients with apical hypertrophic cardiomyopathy and 4 patients with apical tumor. We included a similar number of patients with apical thrombi for comparative analysis (Table I). The final diagnosis was reached in 10 of 11 patients by pathologic evaluation of biopsies or of the masses removed at surgery and necropsy. In a young, asymptomatic Nigerian black man (patient 6), the diagnosis was based on the presence of symmetrically inverted T waves 20 mm deep in the left precordial leads and a "spade-like" narrowing of the apical cavity on 2-D echocardiography, with localized hypertrophy of the apex.[2] The 2-D echocardiograms were recorded in the standard fashion using ultrasound imaging systems (Hewlett-Packard 77020AC or Toshiba SSH-10A) with a 2.25- or 3.5-MHz medium or short focused transducer. The criteria used to define left ventricular thrombus and apical hypertrophy were those stated in previous reports.[1–4] Apical tumor was suspected when the mass did not fulfill the criteria for either thrombus or hypertrophy and showed inhomogeneous ultrasonic appearance, demarcation from but extension into the myocardium, gross or bizarre distortion of the cardiac anatomy and presence of pericardial effusion.[1,5] The 2-D echocardiograms were also evaluated for the presence or absence of 12 specific visual characteristics.

One investigator assessed the recorded history, physical examination, standard 12-lead electrocardiogram (ECG) and chest x-ray (Table I) plus the information that an LV apical mass was present to render a diagnosis. Another investigator assessed the 2-D echocardiograms alone to render a diagnosis, and then he was given the clinical data and again asked to identify the nature of the apical mass. Neither investigator knew the pathologic findings or the proportion of patients with any diagnosis within this study group. Each investigator might choose the single correct diagnosis (+3 points), list an alternative diagnosis after (+2 points) or before (+1 point) the correct one, be unable to choose among the 3 diagnoses (0 points), list only a single but incorrect diagnosis (−1 point) or list only the 2 incorrect diagnoses (−2 points). Thus a perfect diagnosis of all 11 patients would yield

TABLE I Clinical and Pathology Findings in 11 Patients with Left Ventricular Apical Mass

Pt	Age (yr) & Sex	History	Positive Findings (Examination, ECG, X-Ray)	Coronary Disease*	Morphology
1	69M	MI, dyspnea, syncope	CHF, MR, VT, LBBB, cardiomegaly†	LAD, right, LC	Thrombus
2	72M	MI, CVA, chest pain	Old MI, VPCs	LAD, right	Thrombus
3	62M	HBP, MI, LV aneurysm, chest pain, dyspnea, syncope	CHF, MR, old MI, VT, cardiomegaly	LAD, right LC	Thrombus
4	56M	HBP, MI, LV aneurysm, dyspnea	CHF, MR, LVH, old MI, calcified aneurysm, cardiomegaly	LAD, LC	Thrombus
5	73F	HPB, dyspnea, syncope	CHF, MR, AF, St-T changes, LVH cardiomegaly	LC	Apical hypertrophy
6	24M	Car accident	Extreme ST-T changes, LVH	—	—‡
7	60F	Bilateral mastectomy, CVA, chest pain, dyspnea	CHF, AF, VT, ST-T changes cardiomegaly	0	Apical hypertrophy
8	46F	Retroperitoneal mass, CVA, dyspnea	CHF, MR, ST-T changes, lung metastases, cardiomegaly	—	Adenocarcinoma
9	32F	Chest pain	ST-T changes, LVH, VT, cardiomegaly, apical calcifications	0	Fibroma
10	75F	MI, chest pain, dyspnea	CHF, MR, old MI, cardiomegaly, MAC	LAS	Fibroma
11	16F	Mandibular cyst, dyspnea	LBBB, VT, cardiomegaly	0	Fibroma

* Presence of ≥70% coronary obstruction.
† Cardiothoracic ratio >50%.
‡ Diagnosis of apical hypertrophy based on clinical and 2-D echo criteria (see text).
AF = atrial fibrillation; CHF = congestive heart failure; CVA = cerebrovascular accident; LC = circumflex coronary artery; HBP = high blood pressure; LAD = left anterior descending coronary artery; LBBB = left bundle branch block; LVH = left ventricular hypertrophy; MAC = mitral anulus calcification; MI = myocardial infarction; MR = mitral regurgitation; VPCs = ventricular premature complexes; VT = ventricular tachycardia; — = no information available; 0 = absent or negative.

a score of 33; the accuracy and certainty of diagnosis were expressed by a percentage score index (score/33 × 100).

The differential diagnostic accuracy of the methods used is expressed in Table II. The clinical evaluation was useful in defining patients with thrombus and with metastatic cardiac tumor. Because 88 to 99% of cardiac metastases found at necropsy have been associated with primary or secondary intrathoracic malignancy,[6] the x-ray findings of pulmonary masses in patient 8 (Table I) directed the diagnosis to cardiac tumor. Clinical assessment showed 2 major limitations: symptoms and physical examination were noncontributory; and there were no pathognomonic features to aid in recognition of primary cardiac tumors or apical hypertrophy. In 2 of our 3 patients with apical hypertrophy, the ECG showed only nonspecific ST-T changes.[3] A similar ECG pattern, however, was found in most of our patients with tumor. The 2-D echocardiogram improved recognition of apical hypertrophy. Nevertheless, all methods were imperfect in differentiating the apical tumors from thrombi.

There was lack of specificity of visual 2-D echo criteria; 6 of the 12 visual characteristics analyzed were scattered among the 3 categories of masses. These criteria were features related to the mass: strictly apical, symmetric, smooth free edges and presence of calcified areas; and absence of apical diameter narrowing and pericardial effusion. Table III includes the other 6 characteristics that were present in all patients in at least 1 category of mass, although not confined to 1 category necessarily. Wall motion patterns adjacent to and remote from the mass were found to differ in the 3 categories. Patients with thrombus had both local akinesia/diskinesia and abnormal wall motion in areas remote from the mass. All 4 patients with tumor had normal wall motion remote from the apex and 3 of these had severe apical asynergy. All patients with apical hypertrophy had mild apical hypokinesia and normal remote wall motion. Patients with apical hypertrophy had all 6 characteristics listed in Table III in common (i.e., the feature was either present or absent in all). Moreover, active contractility of the mass was a finding specific for these patients, probably representing the major differential diagnostic criterion compared with other categories of apical masses. Our results confirmed the presence of previously described criteria in all patients with thrombi, but revealed their lack of specificity owing to frequent occurrence in patients with tumors. The finding of an apical mass that is visible throughout the cardiac cycle, has clear demarcation from the myocardium adjacent to an area of severe myocardial asynergy,[1,4] and is without active contractility of the mass during systole was present in all of our patients with thrombi, but also was seen in 3 patients with apical tumor (Fig. 1).

These results support the combined use of clinical and 2-D echo data for optimal diagnosis of left ventricular apical masses but additionally suggest the need

TABLE II Diagnostic Accuracy* of Methods Used in Differentiating Left Ventricular Apical Masses

	Thrombus (n = 4)	Apical Hypertrophy (n = 3)	Tumor (n = 4)	Total (n = 11)
Method				
Clinical	100%	44%	50%	70%
2-D echo	100%	88%	50%	78%
2-D echo + clinical	100%	88%	75%	88%

* The diagnostic accuracy is represented for each method studied as achieved score/maximal perfect score × 100 (see text).
2-D echo = 2-dimensional echocardiography.

TABLE III Two-Dimensional Echocardiographic Visual Criteria

	Thrombus	Apical Hypertrophy	Tumor
Abnormal adjacent wall motion	+(A/D)	+(H)	+(H/A/D)
Abnormal remote wall motion	+	0	0
Mass: demarcated from myocardium	+	0	VP
Mass: active contractility	0	+	0
Mass texture			
Different from the myocardium	VP	0	VP
Nonuniform	VP	0	VP

A = akinesia; D = dyskinesia; H = hypokinesia; 0 = absent or negative; VP = characteristic variable but present in most patients in a group; + = present in all patients.

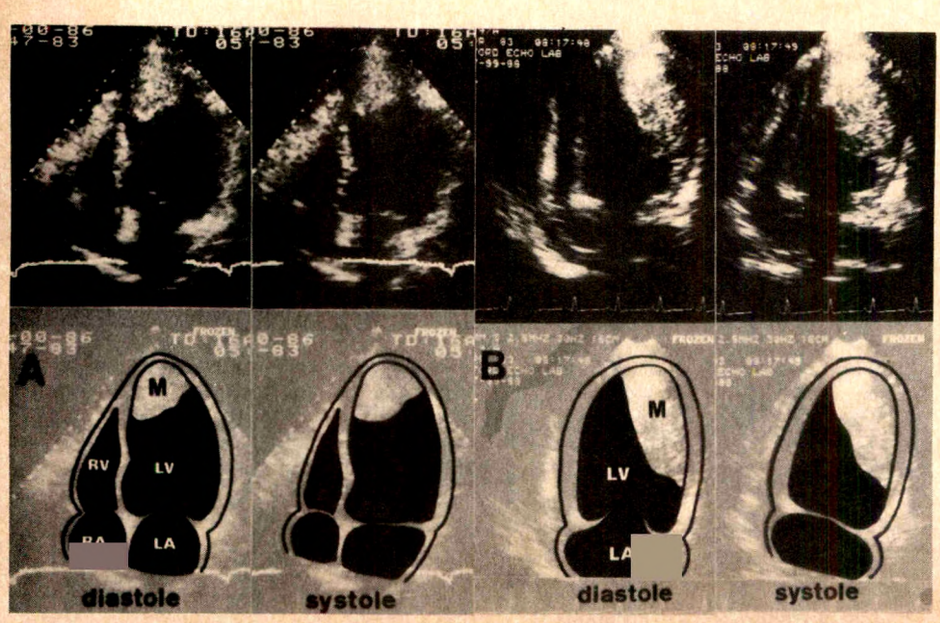

FIGURE 1. Two-dimensional echocardiograms recorded in the apical 4-chamber view in patients with thrombus (**A**) and tumor (**B**). The masses (M) show very similar visual texture characteristics and both are demarcated from the akinetic myocardium. The wall motion remote from the mass was abnormal in **A** and normal in **B.** LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

for improved 2-D echo or other tissue characterization methods to provide more direct information and better segregation of tumors from thrombi. Our few patients with apical hypertrophic cardiomyopathy had several group characteristic 2-D echo features that may help differentiate this entity from apical thrombi.

Pericardial Defect Mimicking a Left Atrial Mass

BARRY S. TALESNICK, MD
FREDERICK J. SUTTON, MD
YU-CHEN LEE, MD
JOSEPH S. McLAUGHLIN, MD

Left atrial (LA) tumor and thrombus are the most common causes of abnormal intraatrial echoes. Extracavitary echoes mimicking intracardiac masses have not been reported. We report a patient with a pericardial defect in whom post-traumatic pericardial adhesions were responsible for the echocardiographic appearance of an LA mass.

A 23-year-old man was referred for 3-artery systolic myocardial bridging. The patient had a 1-year history of retrosternal chest pain after an automobile accident. Examination and chest x-ray were normal. The electrocardiogram displayed a sinus rhythm, a PR interval of 0.24 second and right-axis deviation (160°). Two-dimensional echocardiography (long-axis and subxiphoid views) suggested a large mass fixed to the posterior LA wall behind the posterior mitral valve leaflet (Fig. 1 and 2). The patient underwent incision of the myocardial bridging and LA exploration. No intracavitary mass was visualized or palpated. However, a large, round posterior pericardial defect was seen with the pericardial rim adherent to and compressing the LA wall. Adhesions were lysed between the left atrium and parietal pericardium. A coronary artery bypass graft to the distal circumflex and incision of the left anterior descending myocardial bridge was performed.

Echocardiography had enhanced the clinical ability to recognize intracardiac masses and may have greater sensitivity than any other diagnostic technique.[1] Although false-positive and false-negative studies are occasionally encountered using M-mode echocardiography,[2,3] 2-dimensional techniques tend to clarify confusing studies. In this case we postulate that post-traumatic inflammatory changes in the pericardium contribute to fibrosis and adhesions between the edge of the pericardial defect and left atrium. An extrinsic compressive effect on the posterior left atrium by the fibrotic tissue led to the echocardiographic appearance of a nonmobile LA mass behind the posterior mitral leaflet. The appearance of the pericardial defect suggested a congenital origin. We believe that this is the first reported case of a pericardial defect presenting as an LA mass.

Mitral Valve Prolapse, Wolff-Parkinson-White Syndrome, His Bundle Sclerosis and Sudden Death

XAVIER ANDRÉ-FOUËT, MD
AHMIADZIAH TABIB, MD
PHILIPPE JEAN-LOUIS, MD
DIDIER ANNE, MD
PAUL DUTERTRE, MD
CHRISTIAN GAYET, MD
ALAIN HUYGUE de MAHENGE, MD
ROBERT LOIRE, MD
MAURICE PONT, MD

Case reports of association of mitral valve prolapse (MVP) and Wolff-Parkinson-White syndrome (WPW),[1] of MVP and atrioventricular (AV) block[2] and of WPW and AV block[3] are rare. Reports of sudden death in patients with WPW[4] or MVP[5–8] are also uncommon.

A 19-year-old man who had previously complained of palpitations was admitted to the emergency room for cardiac arrest. Protracted attempts at resuscitation were unsuccessful. An electrocardiogram was not recorded. The only existing electrocardiogram, taken 4 years earlier, showed WPW syndrome type A (Rosenbaum classification) was observed (Fig. 1). Witnesses stated that the patient complained of violent chest pain after being pushed into a swimming pool and then lost consciousness. Postmortem examination of brain, lungs, liver, spleen, adrenal glands, kidneys and digestive tract was normal. Heart examination showed a floppy mitral valve (Fig. 2) and fibrosclerosis of the His bundle.

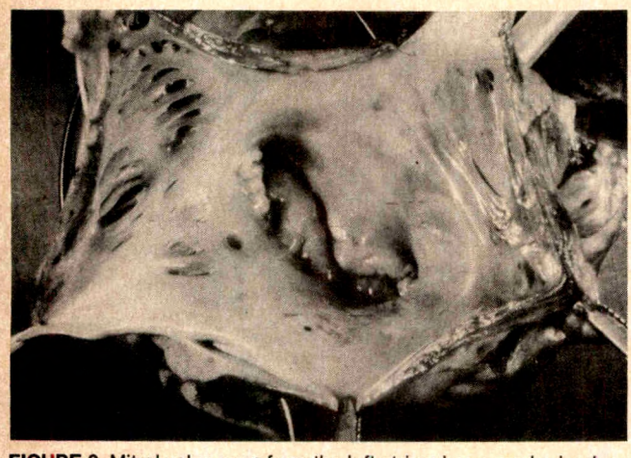

FIGURE 2. Mitral valve seen from the left atrium has a marked redundancy and ballooning of the posterior leaflet.

From the Department of Cardiology, Croix-Rousse Hospital, and the Department of Pathology, Louis Pradel Hospital, at the University Claude Bernard, UER Lyon-Nord and Alexis Carrel, Lyon, France, and from the Cardiac Rehabilitation Center, 69260 Charbonnières-les-Bains, France.

Manuscript received April 8, 1985, accepted April 9, 1985.

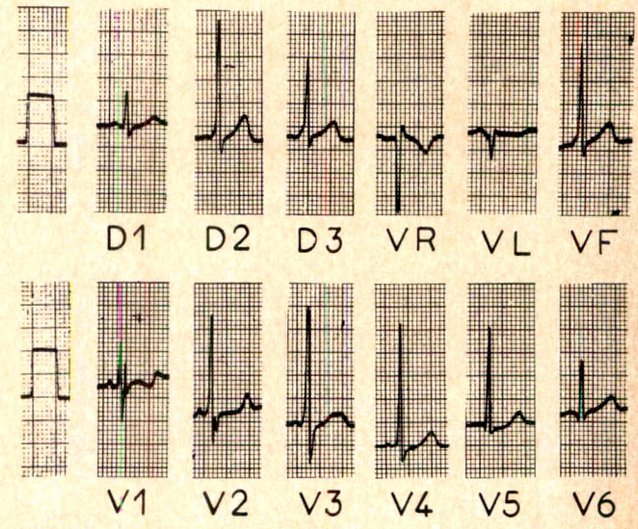

FIGURE 1. Electrocardiogram recorded 4 years before death showing Wolff-Parkinson-White syndrome type A (Rosenbaum classification). Sinus rhythm is 65 beats/min. P-delta = 100 ms; delta wave duration = 50 ms; delta wave positive in V_1, V_2, D_2, D_3 and aVF; negative in aVL.

To our knowledge the association of MVP, WPW syndrome, and His bundle sclerosis has not been described. Is this pathologic association fortuitous or does it indicate a common embryologic origin? No direct relation between MVP and WPW, nor between WPW and AV block has been established. The association between a MVP and involvement of the conduction system, recently reported by Bharati et al,[7] suggests relation between these 2 abnormalities.

Acknowledgment: We thank R. Crane, PhD, and J. Pearson, MD, for their help with translation, and R.M. Jeresaty, MD, Professor of Medicine, University of Connecticut School of Medicine, Hartford, for his critical review of the manuscript.

ONE OF A KIND... IN CHF

Avoid any change in the classic Lasix®-digitalis regimen

BRAND OF furosemide

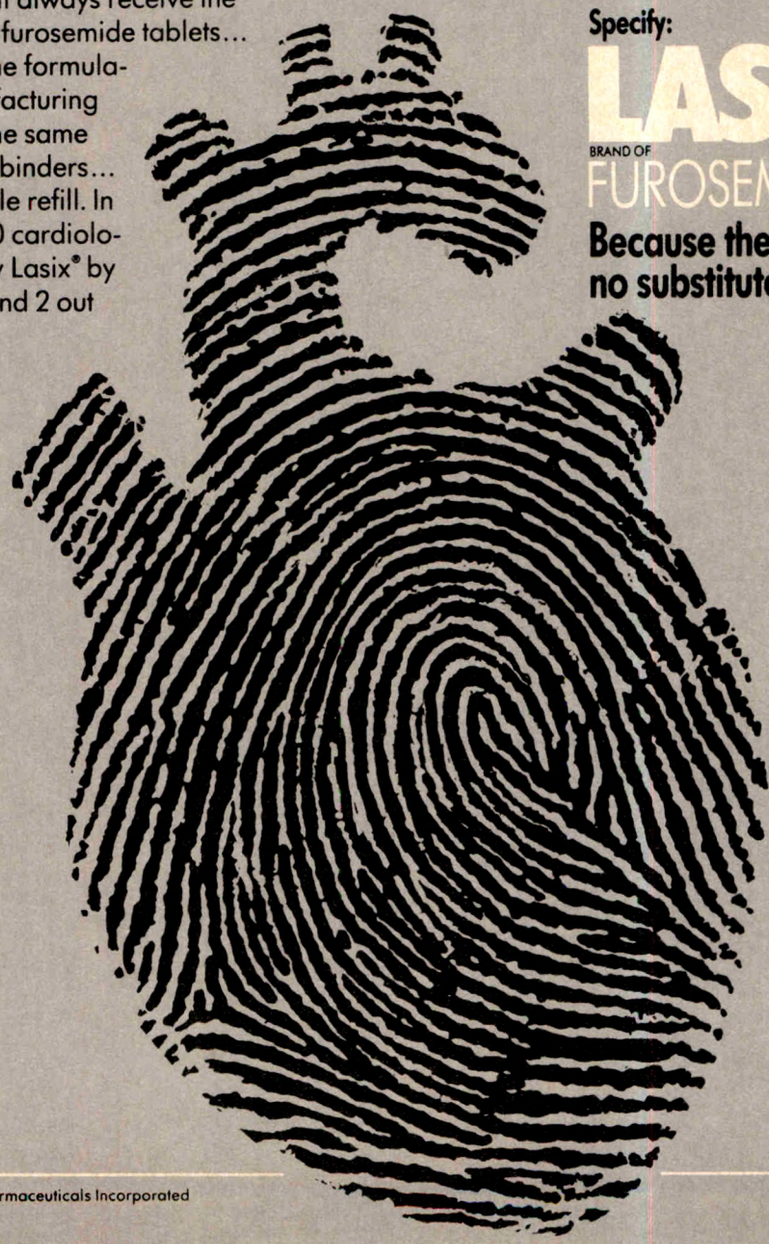
You've titrated to a precise therapeutic response. Now, unless your patient's condition changes, the regimen shouldn't. Because if it does, the sensitive diuretic/digitalis/electrolyte balance could be upset. And the consequences could be serious.

So, once a patient has been stabilized on Lasix® tablets, it's only logical to specify Lasix® by brand name and prevent generic substitution. That's the only way you can be sure your patient will always receive the same brand of furosemide tablets... exactly the same formulation and manufacturing process, with the same excipients and binders... with every single refill. In fact, 9 out of 10 cardiologists do specify Lasix® by brand name, and 2 out of 3 take the extra step to prevent substitution.[1]

Lasix® is the most thoroughly documented drug in its class, with quality so consistent that almost 8 billion tablets have been manufactured without a single product recall.

Reference: 1. National survey of 2960 physicians, including 1502 cardiologists and other physicians subspecializing in cardiology, conducted by Hoechst-Roussel Pharmaceuticals Incorporated, Somerville, New Jersey. August 1982.

Please see following page for brief summary of full prescribing information.



Specify:

LASIX®

BRAND OF FUROSEMIDE 20 mg, 40 mg, 80 mg Tablets

Because there's no substitute for quality

©1985 by Hoechst-Roussel Pharmaceuticals Incorporated

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

PREGNANCY: Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

TOPICS IN HYPERTENSION

Edited by JOHN H. LARAGH, MD

644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $49.00. Available on 30-day approval.

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice. . . and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions by 85 eminent specialists. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

The book is conveniently organized for effective consultation and reading.

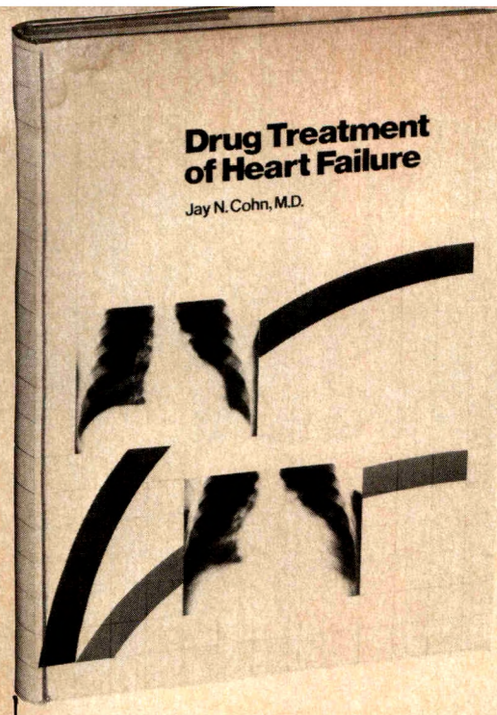
Customers in the following states please include applicable sales tax: CA, CT, GA, IL, MA, MI, NY, OH, PA, TX. All foreign orders must be prepaid in U.S. funds with a check drawn on a U.S. bank or charged to a credit card. Please add $5.00 per book for all orders to be shipped outside the U.S. and Canada.



Drug Treatment of Heart Failure

edited by Jay N. Cohn, MD

0-914316-41-9, approx. 250pp., Oct. '83, $35.00

This volume is aimed at providing clinicians with the physiologic and pharmacologic background necessary to effectively and efficiently create and administer drug therapy regimens for their patients who suffer heart failure. All efforts were made to ensure that the timeliness of each chapter, prepared by internationally respected clinicians and medical scientists, would not be compromised by delays in publication. Consequently, this book presents the very latest thinking on the utilization of drug therapy for heart failure and contains many references as recent as 1982 and 1983. This book is highly recommended to all physicians presently treating patients with heart failure.

TABLE OF CONTENTS AND CONTRIBUTORS

Foreword by Jay N. Cohn, MD

Chapter I
The Treatment of Heart Failure in Perspective: An Overview
by Jay N. Cohn, MD

Chapter II
Pathophysiology of Heart Failure: Deficiency in Cardiac Contraction
by John E. Strobeck, MD, and Edmund H. Sonnenblick, MD

Chapter III
The Role of the Renin—Angiotensin—Aldosterone System in the Pathophysiology of Chronic Heart Failure
by Robert J. Cody, MD, and John H. Laragh, MD

Chapter IV
Pathophysiology of Congestive Heart Failure: The Role of The Kidney
by Norman K. Hollenburg, MD

Chapter V
Congestive Heart Failure: Diagnosis and Principles of Treatment
by Elliot Rapaport, MD

Chapter VI
Conventional Drug Therapy in the Management of Heart Failure
by James E. Doherty, MD

Chapter VII
The Role of Inotropic Agents in the Management of Heart Failure
by Gary S. Francis, MD

Chapter VIII
Vasodilator Therapy of Heart Failure
by Kanu Chatterjee, MB, FRCD

Chapter IX
Captopril in Heart Failure
by William W. Parmley, MD

Chapter X
A Comprehensive Approach to the Treatment of Heart Failure
by Jay N. Cohn, MD

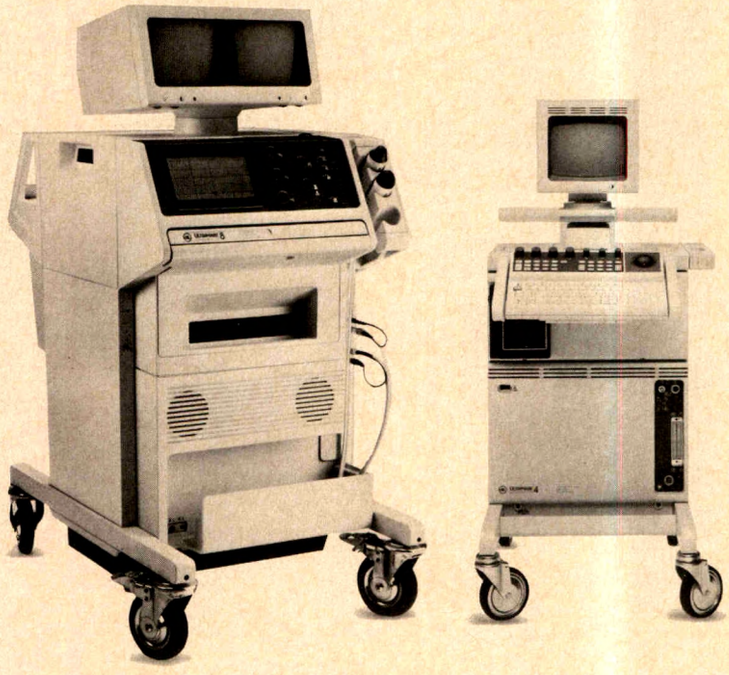
WE'LL GIVE YOU THE FUTURE.

© 1985 ADVANCED TECHNOLOGY LABORATORIES, INC.

NOW.



Ultramark. Echocardiography so advanced, it's ready for applications we haven't yet thought of.

Whatever the future holds for echocardiography, Ultramark has already moved ahead to meet it. So advanced that it performs with unmatched versatility and ease of use today. So advanced, it will support the technologies of tomorrow.

Two completely new systems—combining proven ATL expertise in echocardiography with unparalleled computer power—revolutionize echocardiography as you know it now and effectively conquer the problem of obsolescence. Superb image quality... unprecedented simplicity of operation... sophisticated analysis...broad clinical flexibility ...and unlimited future expansion...for a return on your investment unequaled in echocardiography today.

We urge you to consider Ultramark Ultrasound Systems. This leading-edge technology can keep *you* on the leading edge, clinically, for years to come. Call toll-free 800-982-2011 or return coupon.

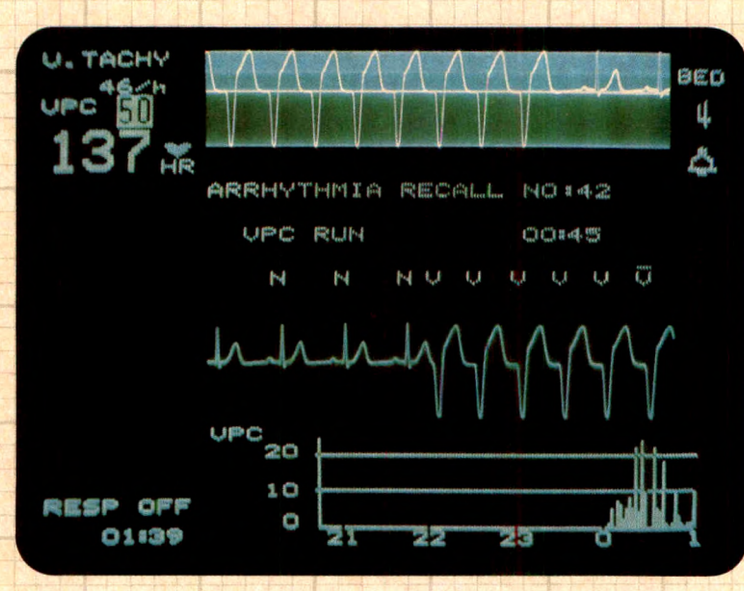
LIGHTING THE WAY WITH SOUND

Lidocaine in the hospital



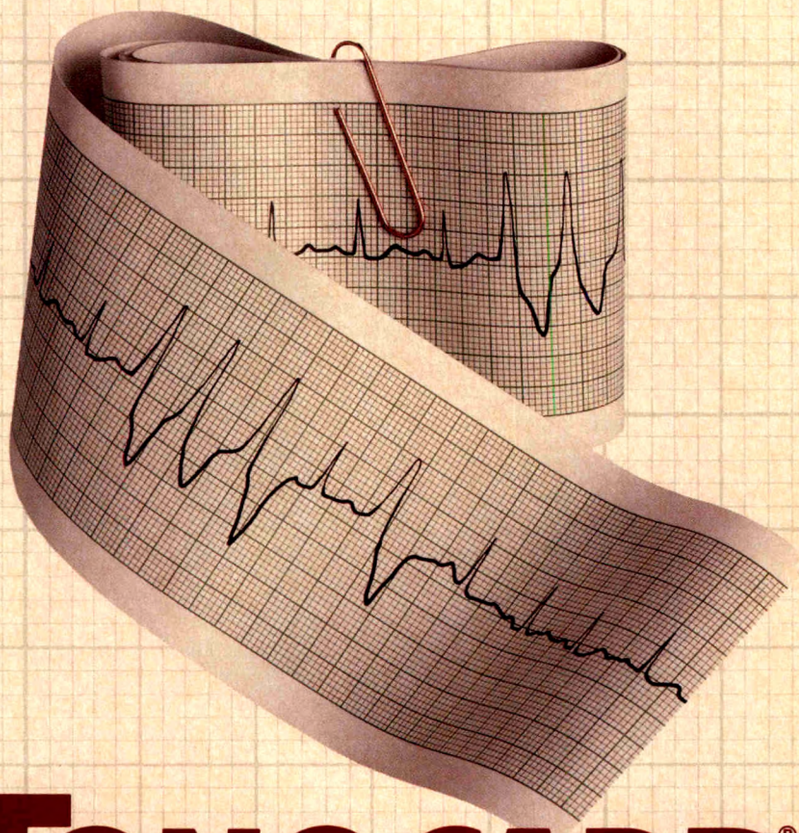
Like other antiarrhythmics, tocainide has not been shown to prevent sudden death, and also, like other antiarrhythmics, it has potentially serious adverse effects including the ability to worsen arrhythmias. Clinical and electrocardiographic evaluation should be used to periodically assess the need for therapy.

TONOCARD® (Tocainide HCl, MSD) is contraindicated in patients who are hypersensitive to this product or to local anesthetics of the amide type and in patients with second- or third-degree atrioventricular block in the absence of an artificial ventricular pacemaker.

Agranulocytosis, bone marrow depression, leukopenia, hypoplastic anemia, and thrombocytopenia have been reported in patients receiving TONOCARD; fatalities have occurred. Blood counts are recommended within the first two to three weeks of therapy and periodically thereafter. See Prescribing Information for details.

For a Brief Summary of Prescribing Information, please see last page of this advertisement.

TONOCARD in the office.



TONOCARD®
(TOCAINIDE HCl|MSD)

For symptomatic ventricular arrhythmias.

Like lidocaine. But it's oral.

A product of Astra/Merck research

MSD

DOHME

® Astra Pharmaceutical Products, Inc.

Copyright © 1985 by Merck & Co., Inc

TONOCARD
(TOCAINIDE HCl | MSD)

MERCK SHARP & DOHME

TONOCARD® (Tocainide HCl | MSD)

Like other antiarrhythmics, tocainide has not been shown to prevent sudden death in patients with serious ventricular ectopic activity, and also, like other antiarrhythmics, it has potentially serious adverse effects, including the ability to worsen arrhythmias. It is therefore essential that each patient given tocainide be evaluated electrocardiographically and clinically prior to, and during, tocainide therapy to determine whether the response to tocainide supports continued treatment.

CONTRAINDICATIONS

Patients who are hypersensitive to this product or to local anesthetics of the amide type.

Patients with second or third degree atrioventricular block in the absence of an artificial ventricular pacemaker.

WARNINGS

Blood Dyscrasias: Agranulocytosis, bone marrow depression, leukopenia, hypoplastic anemia and thrombocytopenia have been reported in patients receiving TONOCARD. Many of these events occurred in patients who were seriously ill and who were receiving concomitant drugs; fatalities have occurred. Since most of these events have been noted during the first 12 weeks of therapy, it is recommended that blood counts, including differential and platelet counts, be performed at least once within the first two to three weeks of therapy; and periodically thereafter, particularly within the first three months of therapy. Blood counts should be performed promptly if the patient develops any signs of infection (such as fever, chills, sore throat, or stomatitis), bruising, or bleeding. If any of these hematologic disorders is identified, TONOCARD should be discontinued and appropriate treatment should be instituted if necessary. Blood counts usually return to normal within one month of discontinuation. Caution should be used in patients with preexisting marrow failure or cytopenia of any type. (See ADVERSE REACTIONS).

Acceleration of Ventricular Rate: Acceleration of ventricular rate occurs infrequently when antiarrhythmics are administered to patients with atrial flutter or fibrillation (see ADVERSE REACTIONS).

PRECAUTIONS

General

Pulmonary Fibrosis: Pulmonary fibrosis, interstitial pneumonitis, fibrosing alveolitis, pulmonary edema, and pneumonia, possibly drug related, have been reported in patients receiving TONOCARD. Many of these events occurred in patients who were seriously ill. The experiences are usually characterized by bilateral infiltrates on x-ray and are frequently associated with dyspnea and cough. Fever may or may not be present. Patients should be instructed to promptly report the development of any pulmonary symptoms such as exertional dyspnea, cough or wheezing. Chest x-rays are advisable at that time. If these pulmonary disorders develop, TONOCARD should be discontinued. (See ADVERSE REACTIONS).

In patients with known heart failure or minimal cardiac reserve, TONOCARD should be used with caution because of the potential for aggravating the degree of heart failure.

Caution should be used in the institution or continuation of antiarrhythmic therapy in the presence of signs of increasing depression of cardiac conductivity.

In patients with severe liver or kidney disease, the rate of drug elimination may be significantly decreased (see DOSAGE AND ADMINISTRATION).

Since antiarrhythmic drugs may be ineffective in patients with hypokalemia, the possibility of a potassium deficit should be explored and, if present, the deficit should be corrected.

Like all other oral antiarrhythmics, TONOCARD has been reported to increase arrhythmias in some patients (see ADVERSE REACTIONS).

Information for Patients

Patients should be instructed to promptly report the development of bruising or bleeding; any signs of infections such as fever, chills, sore throat, or soreness and ulcers in the mouth; or any pulmonary symptoms, such as exertional dyspnea, cough, or wheezing.

Laboratory Tests

As with other antiarrhythmics, abnormal liver function tests, particularly in the early stages of therapy, have been reported. Periodic monitoring of liver function should be considered. Hepatitis and jaundice have been reported in some patients.

Drug Interactions

Specific interaction studies with digoxin and metoprolol have been conducted, no clinically significant interaction was seen with digoxin, but tocainide and metaprolol had additive effects on wedge pressure and cardiac index. TONOCARD has also been used in open studies with digitalis, beta-blocking agents, other antiarrhythmic agents, anticoagulants, and diuretics, without evidence of clinically significant interactions. Nevertheless, caution should be exercised in the use of multiple drug therapy.

TONOCARD is equally effective in digitalized and non-digitalized patients. In 17 patients with refractory ventricular arrhythmias on concomitant therapy, serum digoxin levels (1.1 ± 0.4 ng/mL) remained in the expected normal range (0.5-2.5 ng/mL) during tocainide administration.

Pregnancy

Pregnancy Category C. In a teratogenicity study in rabbits, tocainide was administered orally at doses of 25, 50, and 100 mg/kg/day (about 1 to 4 times the usual human dose). No evidence of a drug-related teratogenic effect was noted; however, these doses were maternotoxic and produced a dose-related increase in abortions and stillbirths. In a teratogenicity study in rats, an oral dose of 300 mg/kg/day (about 12 times the usual human dose) showed no evidence of treatment-related fetal malformations, but maternotoxicity and an increase in fetal resorptions were noted. An oral dose of 30 mg/kg/day (about twice the usual human dose) did not produce any adverse effects.

In reproduction studies in rats at maternotoxic oral doses of 200 and 300 mg/kg/day (about 8 and 12 times the usual human dose, respectively), dystocia, and delayed parturition occurred which was accompanied by an increase in stillbirths and decreased survival in offspring during the first week postpartum. Growth and viability of surviving offspring were not affected for the remainder of the lactation period.

There are no adequate and well-controlled studies in pregnant women. TONOCARD should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers

It is not known whether tocainide is secreted in human milk. Because many drugs are secreted in human milk and because of the potential for serious adverse reactions in nursing infants from TONOCARD, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use

Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

TONOCARD commonly produces minor, transient, nervous system and gastrointestinal adverse reactions, but is otherwise generally well tolerated. TONOCARD has been evaluated in both short-term (n = 1,358) and long-term (n = 262) controlled studies as well as a compassionate use program. Dosages were lower in most of the controlled studies (1200 mg/day) and higher in the compassionate use program (1800 mg and more). In long-term (2-6 months) controlled studies, the most frequent adverse reactions were lightheadedness/dizziness (15.3 percent), nausea (14.5 percent), paresthesia/numbness (9.2 percent), and tremor (8.4 percent). These reactions were generally mild, transient, dose-related and reversible with a reduction in dosage, by taking the drug with food, or by therapy discontinuation. Tremor, when present, may be useful as a clinical indicator that the maximum dose is being approached. Adverse reactions leading to therapy discontinuation occurred in 21 percent of patients in long-term controlled trials and were usually related to the nervous system or gastrointestinal system.

Adverse reactions occurring in greater than one percent of patients from the short-term and long-term controlled studies appear in the following table:

	Percent of Patients Controlled Studies	
	Short-term (n = 1,358)	Long-term (n = 262)
NERVOUS SYSTEM		
Lightheadedness/ dizziness/vertigo/ giddiness	8.0	15.3
Parasthesia/ numbness	3.5	9.2
Tremor/quivering/ tremulousness	2.9	8.4
Confusion/ disorientation/ hallucinations	2.1	2.7
Altered mood/ awareness	1.5	3.4
Restlessness/ shakiness/ nervousness	1.5	0.4
Blurred vision/visual disturbances	1.3	1.5
Discoordination/ unsteadiness/ walking disturbances	1.2	0.0
Anxiety	1.1	1.5
Tinnitus/hearing loss	0.4	1.5
Ataxia	0.2	3.0
Nystagmus	0.0	1.1
GASTROINTESTINAL SYSTEM		
Nausea	15.2	14.5
Vomiting	8.3	4.6
Anorexia	1.2	1.9
Diarrhea/loose stools	0.0	3.8
CARDIOVASCULAR SYSTEM		
Hypotension	3.4	2.7
Bradycardia	1.8	0.4
Palpitations	1.8	0.4
Chest Pain	1.6	0.4
Conduction disturbances	1.5	0.0
Left ventricular failure	1.4	0.0
OTHER		
Sweating/cold sweat/ night sweats/ clammy	5.1	2.3
Headache	2.1	4.6
Tiredness/drowsiness/ fatigue/lethargy/ lassitude/ sleepiness	1.6	0.8
Hot/cold feelings	0.5	1.5
Rash/skin lesion	0.4	8.4

An additional group of about 2,000 patients has been treated in a program allowing for the use of TONOCARD under compassionate use circumstances. These patients were seriously ill with the large majority on multiple drug therapy, and comparatively high doses of TONOCARD were used. Fifty-four percent of the patients continued in the program for one year or longer, and 12 percent were treated for longer than three years, with the longest duration of therapy being nine years. Adverse reactions leading to therapy discontinuation occurred in 12 percent of patients (usually central nervous system effects or rash). A tabulation of adverse reactions occurring in one percent or more of patients follows:

	Percent of Patients Compassionate Use (n = 1,927)
NERVOUS SYSTEM	
Lightheadedness/dizziness/ vertigo/giddiness	25.3
Tremor/quivering/ tremulousness	21.6
Restlessness/shakiness/ nervousness	11.5
Confusion/disorientation/ hallucinations	11.2
Altered mood/awareness	11.0
Ataxia	10.8
Blurred vision/visual disturbances	10.0
Paresthesia/numbness	9.2
Nystagmus	1.1
GASTROINTESTINAL SYSTEM	
Nausea	24.6
Anorexia	11.3
Vomiting	9.0
Diarrhea/loose stools	6.8
CARDIOVASCULAR SYSTEM	
Increased ventricular arrhythmias/PVCs	10.9
CHF/progression of CHF	4.0
Tachycardia	3.2
Hypotension	1.8
Conduction disturbances	1.3
Bradycardia	1.0
OTHER	
Rash/skin lesion	12.2
Sweating/cold sweat/night sweats/clammy	8.3
Arthritis/arthralgia	4.7
Myalgia	1.7
Lupus	1.6

Adverse reactions occurring in less tha one percent of patients in either the co trolled studies or the compassionate use pr gram or since the drug was marketed are follows:

Nervous System: Coma, convulsions/s zures, depression, psychosis, mental chang agitation, altered taste/smell, difficulty co centrating, diplopia, dysarthria, impair memory, increased stuttering/slurred speec insomia/sleeping disturbance, local ane thesia, nightmares, thirst, weakness, mya thenia gravis.

Gastrointestinal System: Abnormal liv function tests, hepatitis, jaundice, (see PR CAUTIONS); stomatitis; abdominal pain/d comfort; constipation; dysphagia; gastroi testinal symptoms (including dyspepsia).

Cardiovascular System: Ventricular fib lation, extension of acute myocardial infar tion, cardiogenic shock, angina, AV bloc hypertension, increased QRS duratio pleurisy/pericarditis, prolonged QT interv right bundle branch block, syncope, vas vagal episodes, cardiomegaly, sinus arrest.

Pulmonary System: Respiratory arre pulmonary edema, pulmonary embolism, p monary fibrosis, fibrosing alveolitis, interstit pneumonitis, pneumonia, dyspnea.

Other: Hematologic disorder (agranuloc tosis, bone marrow depression, hypoplas anemia, anemia, leukopenia, thrombocyt penia), increased ANA, urinary retentio polyuria/increased diuresis, alopecia, ci chonism, claudication, cold extremities, d mouth, earache, edema, fever, hiccups, itc ing, leg cramps, malaise, metallic/menth taste, muscle twitching/spasm, neck pa pain radiating from neck, pallor/flushed fac pressure on shoulder, yawning.

Agranulocytosis, bone marrow depressio leukopenia, hypoplastic anemia, and thromb cytopenia have been reported (0.18 percer in patients receiving TONOCARD in controlle trials and the compassionate use prograr Many of these events occurred in patien who were seriously ill or who were rece ing concomitant drugs; fatalities hav occurred. Most of these events have bee noted during the first 12 weeks of therap (See WARNINGS).

Pulmonary fibrosis, interstitial pneumoniti fibrosing alveolitis, pulmonary edema, an pneumonia, possibly drug related, have bee reported in patients receiving TONOCARI The incidence of pulmonary fibrosis (includir interstitial pneumonitis and fibrosing alveoliti was 0.11 percent in controlled trials and th compassionate use program. These even usually occurred in seriously ill patient Symptoms of these pulmonary disorders an or x-ray changes usually occurred followir 3-18 weeks of therapy and two patients die (See PRECAUTIONS).

HOW SUPPLIED

Tablets containing 400 mg (scored) or 600 m in bottles of 100 and unit-dose packages c 100.

FIRST WE MADE IT GOOD

NOW WE'VE MADE IT EASY

First We Made It Good

From the outset CardioSat programs have been produced under the direction of a distinguished national editorial board and have offered AMA Category I credit.* Received with praise across North America, CardioSat is a highly valued source of CME for many U.S. cardiologists

Now We've Made It Easy

The CardioSat program series has converted to videotape distribution as the primary means of reaching specialists in the field. Pre-recorded, indexed tapes containing accredited programs are mailed to our subscribers who then may truly watch them at their convenience.

The tapes in our CardioSat series form a CME-accredited videotape journal, and subscribers receive:

- 24 half-hour programs on six tapes per year delivered bi-monthly
- registration for 12 hours of CME Category I credit for the subscriber at no additional charge
- up to 12 additional tapes per year on subjects such as malpractice, medical accounting, the use of computers in medicine, and additional specialty programming
- a printed CardioSat yearly program index to facilitate reference to tapes and locations on tapes of specific topics
- information on quarterly CardioSat television programs
- the opportunity to critique programming and become involved in its development.

The New CardioSat: An Important Part of Your Future

If you decide to subscribe, you can do so during a 30-day introductory period for only $195. That's just over $8 per accredited program and includes the special supplementary tapes and other benefits listed previously. The regular subscription price is $295 per year. (If you already are a CardioSat CME-credit subscriber, you will receive a pro-rated refund.)

Authoritative. Timely. And now, convenient. We think you'll agree that CardioSat continuing education programs deserve the reputation they've earned for quality. Now that we've made them easy to get, we also think you'll find them among the best of your CME alternatives.

*The Johns Hopkins University School of Medicine designates this continuing medical education activity for 12 credit hours in Category I of the physician's recognition award of the American Medical Association. The Johns Hopkins University School of Medicine is accredited by the Accreditation Council for Continuing Medical Education to sponsor continuing medical education for physicians.

SAFER FOR

Digoxin therapy with tablets may be compromised by:

☐ many commonly coadministered drugs, eg, antibiotics, antidiarrheals, antacids, and agents that increase or decrease gut motility

☐ concurrent GI disease: diarrhea, malabsorption syndromes, intestinal diseases, constipation

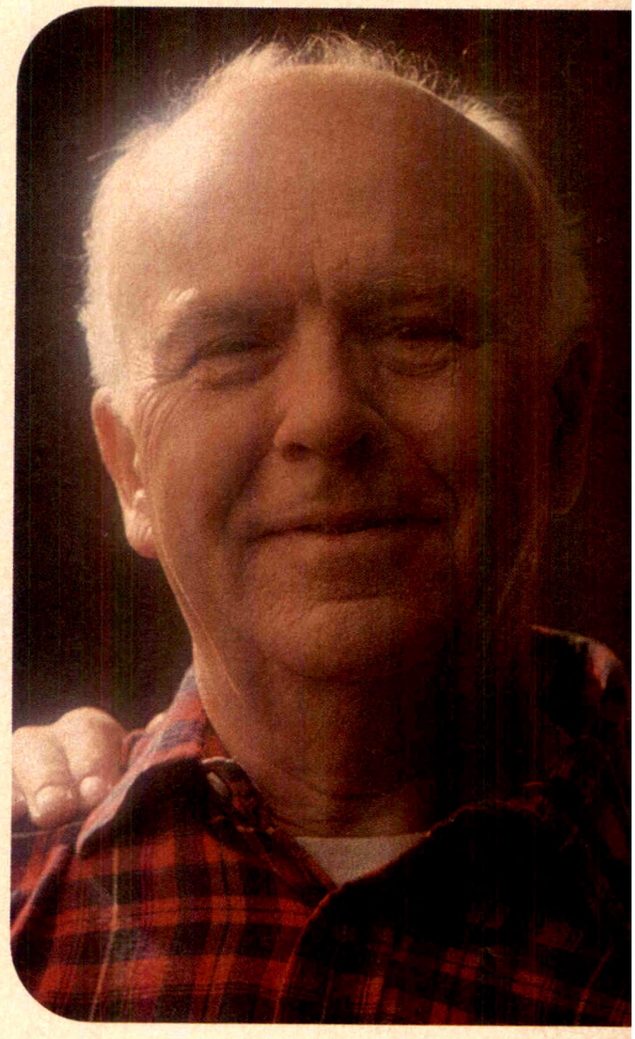
Digoxin therapy with Lanoxicaps® (digoxin solution in capsules) allows the digoxin to be much more rapidly and completely absorbed. Whereas tablet bioavailability is only in the range of 60% to 80%, bioavailability with Lanoxicaps is similar to that following IV administration, 90% to 100%. *Less variability in the amount of digoxin absorbed means less risk of over- or under-digitalization, improving your patient's safety margin.*

"Bioavailability of digoxin has represented one of the most discussed topics of cardiovascular pharmacology of the past decade. The consequent changes in pharmaceutical manufacturing have led to preparations with nearly optimal bioavailability thus favouring a substantial advancement towards a safer treatment."

Levy G, cited by Malini PL, Strocchi E, Negroni S, et al: Greater bioavailability of digoxin in a new capsule preparation. *Current Therapeutic Research* 1983;33:646-650.

"Data collected so far show that if a product is fully bioavailable, the bioavailability in different subjects and in the same subject at different times is within a very narrow range, say 95—100%. However, if a poorly available product has an *average* bioavailability of say 50%, the range in individual patients, and in the same patient at different times, covers a tremendous range, sometimes from 0 to 100%!"

Wagner JG: An overview of the analysis and interpretation of bioavailability studies in man. *Pharmacology* 1972;8:102-117.

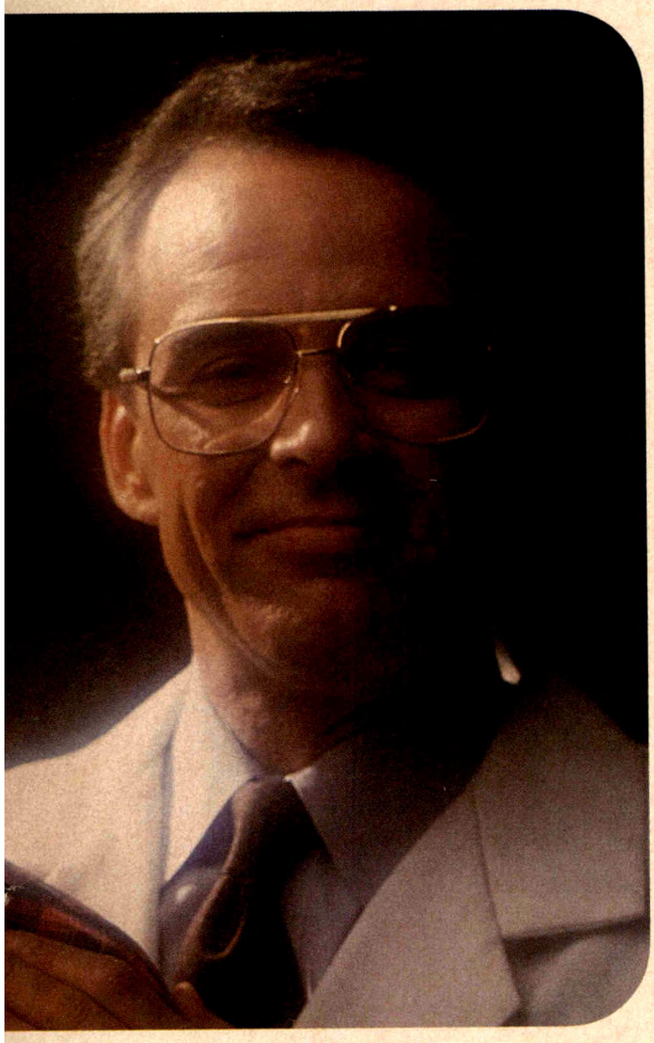


The new standard in digoxin

Copr. ©1984 Burroughs Wellcome Co. All rights reserved.

Please see brief summary of prescribing information on following page.

MA NY PATIE NTS



"The enhanced bioavailability of the capsule formulation and the resulting minimized intersubject and intrasubject variability in serum digoxin concentrations make the capsule dosage form the preferred form of oral digoxin for use in patients who typically have a multitude of factors that can markedly alter digoxin bioavailability."

Johnson BF: Influences of dosage form and other factors on variability in digoxin absorption, in *Digoxin Therapy: The Role of Lanoxicaps®*. Burroughs Wellcome Co., 1983, pp 14-19.

"The more incompletely a drug is absorbed, the more will its absorption vary between patients and in the same patient with time. Drug formulation should always strive for the most complete bioavailability . . . ."

Koch-Weser J: Drug therapy: Bioavailability of drugs (second of two parts). *N Engl J Med* 1974;291:503-506.

100 μg (0.1 mg) I.D. Imprint B2C (yellow)
200 μg (0.2 mg) I.D. Imprint C2C (green)

Brief Summary of Prescribing Information

Before using Lanoxicaps® (digoxin solution in capsules), the physician should be thoroughly familiar with the basic pharmacology of this drug as well as its drug interactions and its indications and usage.

CONTRAINDICATIONS: Digitalis glycosides are contraindicated in ventricular fibrillation. Any untoward effect requiring permanent discontinuation of other digitalis preparations usually constitutes a contraindication to digoxin. Hypersensitivity to digoxin itself is a contraindication to its use. Allergy to digoxin, though rare, does occur. It may not extend to all such preparations, and another digitalis glycoside may be tried with caution.

WARNINGS: The use of digoxin or other digitalis glycosides in the treatment of obesity is unwarranted and dangerous.

It is recommended that digoxin in soft capsules be administered in divided daily doses to minimize any potential adverse reactions. Where compliance is considered a problem, single daily dosing may be appropriate (see DOSAGE AND ADMINISTRATION section in complete prescribing information).

Anorexia, nausea, vomiting and arrhythmias may accompany heart failure or may be indications of digitalis intoxication. Clinical evaluation of the cause of these symptoms should be attempted before further digitalis administration.

Patients with renal insufficiency require smaller than usual maintenance doses of digoxin (see DOSAGE AND ADMINISTRATION section in complete prescribing information).

Heart failure accompanying acute glomerulonephritis requires extreme care in digitalization. Relatively low loading and maintenance doses and concomitant use of antihypertensive drugs may be necessary. Careful monitoring is essential. Digoxin should be discontinued as soon as possible.

Patients with severe carditis, such as carditis associated with rheumatic fever or viral myocarditis, are especially sensitive to digoxin-induced disturbances of rhythm.

Newborn infants display considerable variability in their tolerance to digoxin. Premature and immature infants are particularly sensitive, and dosage must not only be reduced but must be individualized according to their degree of maturity.

Note: Digitalis glycosides are an important cause of accidental poisoning in children.

PRECAUTIONS:

General: Digoxin toxicity develops more frequently and lasts longer in patients with renal impairment because of the decreased excretion of digoxin. Therefore, dosage requirements will be decreased in patients with moderate to severe renal disease (see DOSAGE AND ADMINISTRATION section in complete prescribing information). More time is required to achieve an initial or new steady-state concentration in patients with renal impairment than in patients with normal renal function.

In patients with hypokalemia, toxicity may occur despite serum digoxin concentrations within the "normal range", because potassium depletion sensitizes the myocardium to digoxin. Hypokalemia may result from diuretic, amphotericin B or corticosteroid therapy, and from dialysis or mechanical suction of gastrointestinal secretions. It may also accompany malnutrition, diarrhea, prolonged vomiting, old age and long-standing heart failure. In general, rapid changes in serum potassium or other electrolytes should be avoided, and intravenous treatment with potassium should be reserved for special circumstances as described below (see TREATMENT OF ARRHYTHMIAS PRODUCED BY OVERDOSAGE section in complete prescribing information).

Calcium, particularly when administered rapidly by the intravenous route, may produce serious arrhythmias in digitalized patients. Hypercalcemia from any cause predisposes the patient to digitalis toxicity. Hypocalcemia can nullify the effects of digoxin in man; digoxin may be ineffective until serum calcium is restored to normal.

Hypomagnesemia may predispose to digitalis toxicity. If low magnesium levels are detected in a patient on digoxin, replacement therapy should be instituted.

Quinidine and verapamil cause a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. This rise appears to be proportional to the dose. Due to the considerable variability of these interactions, digoxin dosage should be carefully individualized.

Certain antibiotics may increase digoxin absorption in patients who convert digoxin to inactive metabolites in the gut (see Pharmacokinetics portion of the CLINICAL PHARMACOLOGY section in complete prescribing information). The magnitude of rise in serum digoxin concentration may be as much as two-fold in some cases. This interaction is significantly reduced if digoxin is given as Lanoxicaps.

Patients with acute myocardial infarction or severe pulmonary disease may be unusually sensitive to digoxin-induced disturbances of rhythm.

Atrial arrhythmias associated with hypermetabolic states (e.g. hyperthyroidism) are particularly resistant to digoxin treatment. Large doses of digoxin are not recommended as the only treatment of these arrhythmias and care must be taken to avoid toxicity. In hypothyroidism, the digoxin requirements are reduced. Digoxin responses in patients with compensated thyroid disease are normal.

Reduction of digoxin dosage may be desirable prior to electrical cardioversion to avoid induction of ventricular arrhythmias, but the physician must consider the consequences of rapid increase in ventricular response to atrial fibrillation if digoxin is withheld 1 to 2 days prior to cardioversion. If there is a suspicion that digitalis toxicity exists, elective cardioversion should be delayed. If it is not prudent to delay cardioversion, the energy level selected should be minimal at first and carefully increased in an attempt to avoid precipitating ventricular arrhythmias.

Incomplete AV block, especially in patients with Stokes-Adams attacks, may progress to advanced or complete heart block if digoxin is given.

In some patients with sinus node disease (i.e. Sick Sinus Syndrome), digoxin may worsen sinus bradycardia or sino-atrial block.

In patients with Wolff-Parkinson-White Syndrome and atrial fibrillation, digoxin can enhance transmission of impulses through the accessory pathway. This effect may result in extremely rapid ventricular rates and even ventricular fibrillation.

Digoxin may worsen the outflow obstruction in patients with idiopathic hypertrophic subaortic stenosis (IHSS). Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Patients with chronic constrictive pericarditis may fail to respond to digoxin. In addition, slowing of the heart rate by digoxin in some patients may further decrease cardiac output.

Patients with heart failure from amyloid heart disease or constrictive cardiomyopathies respond poorly to treatment with digoxin.

Digoxin is not indicated for the treatment of sinus tachycardia unless it is associated with heart failure.

Digoxin may produce false positive ST-T changes in the electrocardiogram during exercise testing.

Intramuscular injection of digoxin is extremely painful and offers no advantages unless other routes of administration are contraindicated.

Drug Interactions: Potassium-depleting *corticosteroids* and *diuretics* may be major contributing factors to digitalis toxicity. *Calcium*, particularly if administered rapidly by the intravenous route, may produce serious arrhythmias. *Quinidine* and *verapamil* cause a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. Certain *antibiotics* increase digoxin absorption in patients who inactivate digoxin by bacterial metabolism in the lower intestine, so that digitalis intoxication may result. *Propantheline* and *diphenoxylate*, by decreasing gut motility, may increase digoxin absorption. *Antacids, kaolin-pectin, sulfasalazine, neomycin, cholestyramine* and certain *anticancer drugs* may interfere with intestinal digoxin absorption, resulting in unexpectedly low serum concentrations. *Thyroid* administration to a digitalized, hypothyroid patient may increase the dose requirement of digoxin. Concomitant use of digoxin and *sympathomimetics* increases the risk of cardiac arrhythmias, because both enhance ectopic pacemaker activity. *Succinylcholine* may cause a sudden extrusion of potassium from muscle cells, and may thereby cause arrhythmias in digitalized patients. Although β adrenergic blockers or calcium channel blockers and digoxin may be useful in combination to control atrial fibrillation, their additive effects on AV node conduction can result in complete heart block.

Carcinogenesis, Mutagenesis, Impairment of Fertility: There have been no long-term studies performed in animals to evaluate carcinogenic potential.

Pregnancy: ***Teratogenic Effects:*** Pregnancy Category C. Digoxin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: Caution should be exercised when digoxin is administered to a nursing woman.

ADVERSE REACTIONS: The frequency and severity of adverse reactions to digoxin depend on the dose and route of administration, as well as on the patient's underlying disease or concomitant therapies (see PRECAUTIONS section). The overall incidence of adverse reactions has been reported as 5 to 20%, with 15 to 20% being considered serious (1 to 4% of patients receiving digoxin). Cardiac toxicity accounts for about one-half, gastrointestinal disturbances for about one-fourth, and CNS and other toxicity for about one-fourth of these adverse reactions.

Adults:

Cardiac—Unifocal or multiform ventricular premature contractions, especially in bigeminal or trigeminal patterns, are the most common arrhythmias associated with digoxin toxicity in adults with heart disease. Ventricular tachycardia may result from digitalis toxicity. Atrioventricular (AV) dissociation, accelerated junctional (nodal) rhythm and atrial tachycardia with block are also common arrhythmias caused by digoxin overdosage. Excessive slowing of the pulse is a clinical sign of digoxin overdosage. AV block (Wenckebach) of increasing degree may proceed to complete heart block.

Note: The electrocardiogram is fundamental in determining the presence and nature of these cardiac disturbances.

Gastrointestinal—Anorexia, nausea, vomiting and less commonly diarrhea are common early symptoms of overdosage. Uncontrolled heart failure may also produce such symptoms.

CNS—Visual disturbances (blurred or yellow vision), headache, weakness, apathy and psychosis can occur.

Other—Gynecomastia is occasionally observed.

Infants and Children: Toxicity differs from the adult in a number of respects. Anorexia, nausea, vomiting, diarrhea and CNS disturbances may be present but are rare as initial symptoms in infants. Cardiac arrhythmias are more reliable signs of toxicity. Digoxin in children may produce any arrhythmia. The most commonly encountered are conduction disturbances or supraventricular tachyarrhythmias, such as atrial tachycardia with or without block, and junctional (nodal) tachycardia. Ventricular arrhythmias are less common. Sinus bradycardia may also be a sign of impending digoxin intoxication, especially in infants, even in the absence of first degree heart block. Any arrhythmia or alteration in cardiac conduction that develops in a child taking digoxin should initially be assumed to be a consequence of digoxin intoxication.

The AJC in October 1960

RICHARD E. CLARK, MD

The October 1960 issue of the AJC covered 155 pages, 135 of which were used for scientific articles. Two-thirds of the issue (82 pages) was used for a symposium on anesthesia for cardiac surgery. One must recall that this was an emerging clinical speciality in an era of a mortality rate that was approximately 20%.[1] The symposium had contributions by 14 centers then engaged in open-heart surgery. These reports came from Boston, New York, Los Angeles, Cleveland, Durham, Miami, Washington, D.C., Philadelphia and Baltimore. A major concern during this period was the myocardial depressant effects of the various anesthetic agents customarily used for other types of patients and operations.

These anesthetic agents—diethyl ether, halothane, thiopental sodium and cyclopropane—were the principal agents being tested on isolated hearts, in dogs and in an uncontrolled nonrandomized way in patients. The additive effects of induction, premedication agents and relaxants also were studied.

In the laboratory, it was evident that light anesthesia made little change in right ventricular stroke volume and left ventricular stroke work.[2] Clinically, however, deeper planes of anesthesia were required and untoward effects were observed. A combination of ether and barbiturate and a parasympathetic antagonist caused a decrease in heart rate, an increase in stroke volume, and an increase in blood pressure and total peripheral resistance, with a mild to moderate decrease in cardiac output. Depressive effects particularly those of diethyl ether, cyclopropane and halothane were concentration-dependent.

Each unit appeared to adopt special monitors for measurement of a variety of variables in cardiac surgery. Among these were a variety of signal conditioners and recorders for the measurement of the electrocardiogram, the electroencephalogram, and various pressures as well as an enormous effort for the measurement of whole blood pH, P_{CO_2}, and P_{O_2} and temperature in various locations in the body. Blood gas analyzers were in their infancy. These devices required an incredible amount of technical skill to calibrate both pH and P_{CO_2} over a wide range. The physiologic importance of correction of values to 37°C had not been appreciated nor the fact that hypothermic animals became alkalotic.

Although rarely used today, electroencephalography occupied a major role in the measurement responsibilities of the anesthesiologist in 1960. The separation between cerebral hypoxemia and hypothermia was difficult, although it was clear in catastrophic cases that the electroencephalogram changed dramatically during the operation. An ear oximeter using infrared light was believed to be efficacious and was one of the earliest demonstrations of an effort toward noninvasive determination of the O_2 content of the arterialized blood during cardiopulmonary bypass. Monitoring was achieved with devices that had been adapted from the cardiac catheterization laboratory and recorders used both heated styluses and mirrored galvanometry and light-sensitive paper.

The conduct of cardiopulmonary bypass was of special interest because so many of the intraoperative and postoperative problems appeared to be associated with its use. Two general types of oxygenators were used: the screen (Gibbon) or the disc (Kay-Cross). Each required priming with large volumes of whole blood.[3–7]

Blood volume requirements for cardiac surgery caused enormous concern, and this led to a series of experiments and determinations by many centers of circulating blood volume by use of I-131 and chrominum-51 before, during and after cardiopulmonary bypass. The problems, in great part, could be traced to the fact that the extracorporeal circuit had a volume that was equal to or greater than the patient. Hemodilution with crystalloid prime was not thought possible with the devices in use until the laboratory work of Neptune et al demonstrated efficacy.[3] These data from dogs and patients were not accepted readily by the clinical community for several years.

The immediate postoperative interval was the most difficult for anesthesiologists, cardiac surgeons and intensive care unit nurses. It was quickly learned that volume-controlled ventilators were necessary and that a major characteristic of the immediate postoperative interval was an alveolar-capillary block, which was related to a phenomenon of water and protein extravasation into the pulmonary interstitium. This was later traced to the large volumes of unfiltered blood and crystaloid given in the prime and during the procedure. Although most heart-lung machines had arterial

line filters, the pore size was large. The quantity and size of the solid microemboli in the stored blood and the perfusate were not appreciated.

Postoperatively, low cardiac output was common. Whether or not the use of Melrose's solution[4] was responsible or the use of anoxic arrest was the cause were not answered in the symposium. Improved methods of protection of the heart were clearly needed, and either method was hazardous allowing precious few minutes for repair of complex lesions. The agent of choice for poor contractility was digitalis in the form of ovabain because of its rapid onset of action.

Arrhythmia was a major problem with the early advent of closed- and open-heart surgery. Most arrhythmias were believed to be a result of inadequate oxygenation and carbon dioxide accumulation or were secondary to hypotention from blood loss or anesthetic agents. All reports emphasized that the minimal amount of anesthesia must be given and that careful attention to hyperventilation and avoidance of metabolic acidosis was mandatory. An arterial pH >7.45 was recommended regardless of temperature, and this was primarily done through hyperventilation, which was the hallmark of the management of early anesthesia.

The era of open-heart surgery was just beginning. The Los Angeles group reported that anesthesia had been given over a 4-year interval to 164 patients who had undergone cardiac operation with the use of cardiopulmonary bypass and hypothermia and general anesthesia was given to 68 patients for the performance of a cardiac procedure.[5] At that time, most patients (548) were anesthetized for cardiac catheterization.

Of historical interest was the report from Cleveland in which 429 consecutive cardiac surgical patients had a hospital mortality rate for the Beck I operation of 6% over a 5-year interval, the last 200 patients having a 2% hospital mortality rate.[6] This operation consisted of abrasion of the pericardium by mechanical means and application of trichloracetic acid and powdered asbestos. Additionally, a suture, placed from the external surface of the heart, surrounded the coronary sinus, narrowing it to approximately 3 mm. The theory was that the resulting congestion increased coronary sinus pressure, which would stimulate the development of intercoronary anastomoses within the ischemic myocardium. These operations were done through a left lateral thoracotomy without cardiopulmonary bypass and were followed by intercostal blockade with tetracaine.

The remaining one-third of the reports covered a variety of topics. One involved the problem of heart failure, which occurred in the immediate postpartum interval and was found to be related to the presence of heart disease in practically all patients. Another involved the relation between the cerebral circulation and arrhythmia, and Corday and Irving[7] reported that there was an intimate relation between the two. The cerebral circulation was also studied by Wolfe,[8] in Cleveland, who attempted to simulate the clinical situation of ventricular fibrillation under 2 conditions, normothermia and mild hypothermia (31°C). Even mild hypothermia provided protection against cerebral damage. An anecdotal article of historical note involved the notes by Thomas Bevel Peacock on dissecting aneurysm as he had observed it in 1843. He reported 5 cases to which he appended 14 from the published reports and attempted to develop a theory of pathogenesis and life history.

A variety of case reports followed. One involved congenital tricuspid stenosis, indeed a rarity both then and now. An aneurysm of the right coronary artery was described with rupture into the right atrium, with 1-year survival. Additionally, the problem of neonatal digitalis intoxication through the placenta was described in a mother requiring this compound. Wenckebach's phenomenon associated with hyperparathyroidism and the problem of the atypical patent ductus arteriosis were reviewed. The October issue contained the abstracts from the Ballisticardiographic Research Societies. In the President's column, the educational mission of The American College of Cardiology was emphasized. At that time, the college's annual meeting was held jointly with the American Heart Association. The ninth interim meeting of the American College of Cardiology's program was printed, and most prominent among these were so-called firestone conferences, which covered an enormous range of topics.

FROM THE EDITOR

Mitral Valve Prolapse and Systemic Hypertension

In the USA there are approximately 160 million persons over 20 years of age (total population = 238 million). Of the 160 million, an estimated 8 million (5%) have auscultatory evidence of mitral valve prolapse (MVP) and 60 million (37%) have systemic hypertension (SH) (arterial pressure $\geq$140/90 mm Hg). Accordingly, of the 8 million with MVP, nearly 3 million (0.37 $\times$ 8) have SH, and of the 60 million with SH, 3 million (0.05 $\times$ 60) have MVP. The number of persons, therefore, with both MVP and SH in the USA is substantial.

Except in the person with left ventricular outflow obstruction, the systemic peak systolic arterial pressure is identical to the left ventricular peak systolic pressure, which of course is the pressure that closes the mitral valve orifice during ventricular systole. The normal mitral valve withstands elevation of the left ventricular peak systolic pressure without development of mitral regurgitation unless mitral anular calcific deposition is heavy, a process which is more frequent in hypertensive than in normotensive persons.[1] But how well does the defective, i.e., prolapsed or floppy, mitral valve tolerate chronic elevation of the left ventricular peak systolic pressure? My answer is "poorly," and the reason is because the associated SH (specifically, the elevated left ventricular systolic pressure) greatly increases the frequency of spontaneous rupture of mitral chordae tendineae, an occurrence virtually limited to patients with preexisting MVP. Jeresaty and associates[2] found underlying MVP in 23 (92%) of 25 patients with spontaneous rupture of mitral chordae tendineae and Hickey and associates[3] found underlying MVP in 29 (94%) of 31 patients with spontaneous rupture of mitral chordae tendineae. In an earlier study,[4] my colleagues and I examined 60 operatively excised purely regurgitant prolapsed mitral valves: 13 had ruptured chordae tendineae and of these, 11 (85%) had had SH before valve replacement; of the remaining 47 valves, none had ruptured chordae tendineae and only 11 (23%) of them had had SH preoperatively.

The normal mitral leaflets, as with the leaflets of all 4 cardiac valves, consist of 2 components: the fibrosa and the spongiosa. The fibrosa consists of collagen fibrils and the spongiosa, of an acid mucopolysaccharide material. In MVP the collagen fibrils of both the leaflets and chordae tendineae are defective[5] and probably, at least initially, decreased in number, and the spongiosa material, the "weaker" of the 2 components, is present in excessive amounts. It is reasonable to believe that the weaker the mitral leaflet and chordal structures, the greater the effect on them of the left ventricular systolic pressure, and the greater the mitral closing pressure the greater its effect on the defective mitral leaflet and chordal structures.

In summary, the normal mitral valve tolerates elevated left ventricular systolic pressures (mitral closing pressures) well, i.e., without creating mitral regurgitation and without rupturing mitral chordae tendineae. The prolapsed mitral valve, in contrast, contains defective collagen fibrils and excess spongiosa and it appears to withstand elevated left ventricular systolic pressures poorly as manifested by a high frequency of spontaneous rupture of chordae tendineae (and probably also by an increased degree of leaflet prolapse). Thus, proper treatment of SH may prevent or delay the appearance of severe mitral regurgitation that occurs in some patients with MVP.

RELATION BETWEEN ELECTROCARDIOGRAPHIC AND SCINTIGRAPHIC LOCATION OF MYOCARDIAL ISCHEMIA IN 1-VESSEL CORONARY ARTERY DISEASE

In the report of Fox et al[1], the investigators claimed that no studies had satisfactorily addressed the problem of whether the exercise electrocardiogram (ECG) can locate the site of ischemia, and quoted our recent article.[2] Apart from minor methodologic differences in exercise testing and analysis of thallium scans, the protocol used by Fox et al. was identical to our own. The same criteria for patient selection were used, i.e., only patients with 1-vessel coronary artery disease (CAD), interpretable ECGs and no previous myocardial infarction were included, and an independent method (thallium scan) was used to document and locate ischemia. The only difference between the 2 studies was that 18% (not 25% as quoted by Fox et al) of our patients with 1-vessel CAD had normal thallium scans, whereas all patients in the study of Fox et al had reversible defects. It is well known that the thallium scan does not have 100% sensitivity in detecting patients with 1-vessel CAD as was reported in a previous study from the same group.[3] Certainly, the exclusion of patients without thallium defects confers no unique advantage on the study as claimed by Fox et al. We were nevertheless pleased that Fox et al confirmed our finding that ST-segment depression on the 12-lead exercise ECG did not predict the anatomic site of ischemia.

BUCINDOLOL

We were interested in the recent study by Rotmensch et al (Am J Cardiol 1984;54: 353–356). We also had experience with bucindolol in 8 patients. The duration of action of bucindolol may not be as long as proposed by Rotmensch et al, because we observed significant changes in blood pressure 1 hour after a 150-mg dose was administered, which was not seen 10 hours later (Table I). Doses of bucindolol <150 mg produced less antihypertensive response suggesting that 150 mg is an effective dose. We also can confirm the partial intrinsic sympathomimetic action of bucindolol because there was a dose-related inhibition of exercise-induced tachycardia, whereas the pulse rate at rest remained unchanged.

It also has been suggested that bucindolol may have another beneficial action, α-blocking activity. This α-receptor blockade would theoretically offset some of the β-receptor-induced bronchoconstriction in the lung. We previously demonstrated that labetolol (an α-β-receptor blocker) produced bronchoconstriction of a similar degree to the most cardioselective β-receptor blocker, atenolol.[1] Bucindolol in our study produced no effect on peak flow FEV_1 and FVC in our study suggesting that it may be as safe as the more selective β blockers. One small point of caution: We observed increases in the skeletal creatine kinase in 3 patients, which normalized in 2 on cessation of therapy. In 1 patient, elevated creatinine kinase has persisted for 1 year. Increases in creatine kinase have been reported with other β blockers possessing intrinsic sympathomimetic action,[2] but we believe that careful observation is necessary.

SERIAL ELECTROPHYSIOLOGIC TESTING AFTER ACUTE MYOCARDIAL INFARCTION

Long-term reproducibility of recurrent sustained ventricular tachycardia (VT) by programmed electrical stimulation is taken as a priori by many electrophysiologists. Therefore, the report by Schoenfeld et al[1] is a welcomed confirmation of the anecdotal experiences of others. We reported our anecdotal experiences in 2 recent case reports.[2,3] Unlike Schoenfeld et al, our focus has been to address the long-term reproducibility of sustained VT shortly after acute myocardial infarction (AMI). There is evidence that patients with complex ventricular arrhythmias, occurring in the recovery phase of AMI are at an increased risk for sudden death in the first year. Because many of these high-risk patients do not die in the succeeding year, one might conclude that their early electrical instability may have changed with time. Our first report[2] addressed the concept that induced sustained VT in a patient early after AMI may not be replicated at 20 months. This patient was well 4 years after AMI. In our second study (Luck et al[3]), we reproduced sustained VT on 5 occasions after an anterior AMI in a high-risk patient over a 15-month period. This second patient has never had spontaneous sustained VT and remains asymptomatic without antiarrhythmic therapy 3 years after AMI. We believe that long-term reproducibility of VT by electrical stimulation may be more important in patients with sustained VT after AMI. If arrhythmias are not inducible after 1 to 2 years, then the prognosis may clearly be different. Likewise, empirical therapy or therapy with programmed electrical stimulation after AMI may be discontinued after 1 to 2 years if a repeat study reveals negative results.

Transderm-Nitro®

(nitroglycerin)
Transdermal Therapeutic System

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE
This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.
In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.
Transdermal nitroglycerin systems should be removed before attempting defibrillation or cardioversion because of the potential for altered electrical conductivity which may enhance the possibility of arcing, a phenomenon associated with the use of defibrillators.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.
Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.
Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.
The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response. The Transderm-Nitro 2.5 system is useful principally for decreasing the dosage gradually, though it may provide adequate therapy for some patients when used alone.
The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.
Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

HOW SUPPLIED

Transderm-Nitro System Rated Release *in vivo*	Total Nitroglycerin in System	System Size	Carton Size

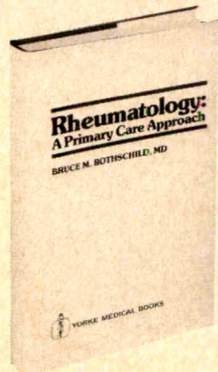
The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind



Rheumatology

A Primary Care Approach

Written by:
Bruce M. Rothschild, MD
Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V.A. Medical Center North Chicago, Illinois

ISBN 0-914316-33-8, $42.50, 430 pp., illus., 1982.

What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

Abbreviated Table of Contents

Section 1 **Investigative Techniques**
Section 2 **Patterns**
Section 3 **Management**

"This compact, well-designed and generally informative volume is a useful reference for the management of rheumatic disease by physicians who deliver primary care. The family physician will undoubtedly use this frequently as a reference."
Charles M. Plotz, MD American Family Physician

"This book is a good primer for students, residents, and health professionals who would like a glimpse into rheumatology. It can be recommended for all but the specialist (but perhaps the specialist should read it, too, to see what those he is training are learning)."
George E. Ehrlich, MD JAMA September '83

This is a superb text by a sensitive, concerned, organized author of international repute . . . Each chapter is well outlined, concise, practical, and has a current and appropriate bibliography at the end . . . a skillfully structured text which is a quality contribution . . . a very readable text."
John A. Feagin, Jr., MD Military Medicine March '83

Deliver medication and monitor at the same site at the same time.

Why compromise drug delivery to monitor cardiac output or the other way around? Now there's a true five-lumen thermodilution catheter that lets you do both at the same site simultaneously. It's new from Gould... for added convenience and patient safety in critical care.

But that's not all that's unique about the PentaCath.™ Its circular lumen design increases interlumen wall thickness which minimizes the possibility of catheter kinking and improves the quality of pressure waveforms. The PentaCath AV, Model SP5527, has a special RV port for measuring right ventricular pressure when clinical situations demand it. With all PentaCath models, you can monitor right atrial, pulmonary artery and pulmonary capillary wedge pressures as well.

The PentaCath is heparin bonded to reduce thrombogenicity. Balloon quality is exceptional, with excellent symmetry and total tip coverage for better protection against ventricular irritation.

Combined with Gould's advanced, portable Hemodynamic Profile Computer and closed loop CritiKit™ Injection Kit, the PentaCath offers greater convenience, accuracy and enhanced patient care. Without compromise.

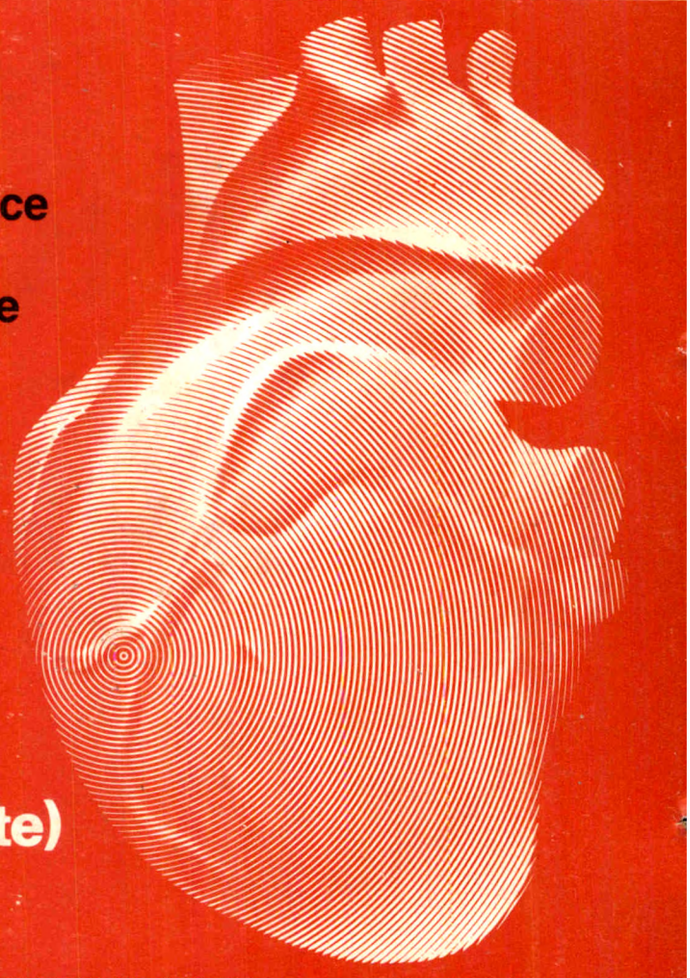
The Pacekeeper™

For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.



CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

DICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after ntaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V ctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when apy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete rtblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, mplete bundle branch block or other severe intraventricular conduction defects, myasthenia vis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial illation with rapid ventricular response, use digitalis to control ventricular rate prior to administra- of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by gressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high rticular rate. This potential hazard may be reduced by digitalization prior to administration of nidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered currently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence uinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or rticular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or e clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by assium and reduced in the presence of hypokalemia. Quinidine should be used with extreme tion in the presence of incomplete A-V block, since complete block and asystole may result. nidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting al, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in ma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be inistered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and rmination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are inistered. Periodic blood counts and liver and kidney function tests should be performed during -term therapy.

DRUG INTERACTIONS OF QUINIDINE:

DRUG	EFFECT
With anticholinergic drugs	Additive vagolytic effect.
With cholinergic drugs	Antagonism of cholinergic effects.
With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine.
With coumarin anticoagulants	Reduction of clotting factor concentrations.
With tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade.
With phenothiazines and reserpine	Additive cardiac depressive effects.
With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine.
With digoxin	Increased plasma concentrations of digoxin (see WARNINGS).

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases where the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: The drug should be used with caution due to excretion of the quinidine in breast milk. ADVERSE REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/or disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTESTINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricular tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMATOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, and syncope; disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intense pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Full Prescribing Information.

A Symposium: Esmolol—An Ultrashort-Acting Intravenous Beta Blocker

Introduction

EDMUND H. SONNENBLICK, MD

Beta-adrenergic stimulation with resultant tachycardia, systemic hypertension and arrhythmia may produce adverse consequences in many acute settings, and long-term control of these effects by β-adrenergic blockade is well established. In ischemia, reduction of heart rate, contractility and blood pressure reduces myocardial oxygen consumption, while the prolonged duration of diastole, which occurs with a slower heart rate, enhances diastolic coronary blood flow. For these reasons, β-adrenergic blocking agents have been effective not only in the treatment of chronic ischemia (angina), but also in aborting impending myocardial infarction with unstable angina and intermediate syndromes. Reduction of the extent of myocardial infarction, once the process has advanced beyond reversible ischemia, is much less clear. Thus, β-adrenergic blocking agents have much to offer therapeutically in early ischemia. However, the prolonged action of available β blockers complicates their use in acute settings because withdrawal of sympathetic tone when extensive myocardial necrosis may have already occurred and impending failure has ensued could be detrimental. Moreover, bronchospasm or conduction defects may occur idiosyncratically. Thus, the availability of a β-blocking agent such as esmolol, whose action is rapid in onset, can be titrated and very rapidly terminated when required, would provide an important safety factor in these settings while testing and treating the acute problem. The same applies for use of such an agent to treat rapid supraventricular tachycardias.

This symposium was held to review the information available on esmolol. It begins with an overview of the basic pharmacology by Dr. Gorczynski, who concludes that esmolol is a cardioselective β blocker with minimal partial agonist activity or membrane depressant properties and has a half-life of approximately 9 minutes.

Dr. Lowenthal describes the clinical pharmacology, pharmacodynamics and drug interaction studies with esmolol. He confirms the pharmacologic profile of esmolol in humans and reports no clinically important effects on vital signs, blood chemistry, hematology or drug interactions. The clinical electrophysiology of esmolol is described by Dr. Greenspan as typical of, and

of comparable intensity to, other β blockers. Its unique advantage is its rapid onset and reversal of electrophysiologic effects, making it particularly suited for acute antiarrhythmic intervention in clinical situations in which the risk of untoward effects of β blockade is high. Hemodynamic studies by Dr. Iskandrian, who used noninvasive techniques, demonstrate typical β-adrenergic blocking effects with esmolol. Because the efficacy of esmolol in supraventricular tachycardia has been established, Dr. Morganroth undertook a study to compare esmolol to propranolol for treatment of supraventricular tachycardia. He concludes that esmolol, because of its short half-life and efficacy equal to propranolol, has marked advantages in the control of supraventricular tachyarrhythmia in patients in the intensive care unit.

Drs. Kloner, Kirschenbaum and colleagues describe the results of the only study to date of esmolol in patients with acute ischemia or infarction. They conclude that esmolol is safe and effective in lowering heart rate and arterial pressure (and, hence, rate-pressure product) in patients with acute myocardial ischemia and infarction and that hemodynamic effects are rapidly reversed after termination of the infusion. In patients with acute ischemia in whom oxygen demand should be reduced, but in whom β blockade may precipitate heart failure, bronchospasm, conduction abnormalities or hypotension, esmolol may be safer to use than conventional longer-acting β blockers.

In another acute, intensive care setting Dr. Gray compared the effects of esmolol and nitroprusside in postoperative hypertension in a crossover study. For hypertension early after cardiac surgery, he concludes that esmolol is safe, effective and rapid in onset, and when compared with nitroprusside, results in less unwanted decrease in diastolic blood pressure and oxygen saturation. In addition, heart rate and cardiac index are decreased with esmolol, as one anticipates from the use of β-adrenergic blocking agents in general.

Another potential clinical application of esmolol is in the control of perioperative tachycardia and hypertension in surgical patients at high risk of cardiac ischemia. This was studied by Dr. Reves, who believes that its rapid onset and elimination make esmolol particularly well suited for preventing and treating the adrenergic responses to intraoperative stresses, which may be very intense but are often brief.

This early experience with esmolol suggests that it will provide an important option to therapy in acute clinical settings. We look forward eagerly to the results of ongoing studies in acute ischemic settings as well as other indications for the use of esmolol.

Basic Pharmacology of Esmolol

RICHARD J. GORCZYNSKI, PhD

Preclinical studies show that esmolol is an ultrashort-acting, cardioselective β blocker that possesses minimal partial agonist action or membrane-depressant properties. The electrophysiologic and hemodynamic actions of esmolol are the result of β blockade. No direct, β receptor-independent cardiovascular actions have been identified with β-blocking doses in laboratory experiments. Because esmolol slows atrioventricular conduction, increases atrioventricular refractoriness and decreases the determinants of myocardial oxygen demand, it should have use in the treatment of supraventricular tachycardias and acute myocardial ischemia. Esmolol, because of its ultrashort duration of action, should be safe for the induction of β blockade in patients who are critically ill and is ideally suited for rapidly changing levels of β blockade in this clinical situation.

(Am J Cardiol 1985;56:3F–13F)

Beta blockade has become a well-accepted treatment for various cardiovascular diseases, including supraventricular tachyarrhythmias, hypertension and angina pectoris.[1,2] Recently β blockade has been shown to decrease the long-term mortality rate of survivors of acute myocardial infarction.[3,4] Although use of β blockade in reducing ischemic damage and incidence of primary ventricular fibrillation during the acute phase of myocardial infarction has been supported by several recent clinical trials,[5–7] the efficacy of β blockers in this setting has not been proved[8,9] and necessarily depends on how soon after the onset of symptoms therapy can be instituted.

The efficacy of β blockers in the treatment of supraventricular tachyarrhythmias hinges on their well-known effect of slowing conduction through, and of increasing the refractoriness of, the atrioventricular (AV) node. These actions are primarily a result of inhibition of sympathetic influences via blockade of β receptors.[10]

It is generally accepted that some degree of sympathetic activation accompanies acute ischemic insults to the heart as a result of either physiologic or psychologic stimuli or both.[11,12] Moreover, ample evidence shows that in the presence of a defect in oxygen delivery to the myocardium, increases in sympathetic tone can initiate ischemia, infarction and arrhythmia by producing an increase in myocardial oxygen demand and perhaps in some instances by further reducing myocardial oxygen supply. Because the deleterious effects of sympathetic activity on the heart are mediated primarily via β-adrenergic receptors, β blockade can lessen the severity of ischemia by reducing the heart's oxygen need and, possibly, by augmenting myocardial oxygen supply.[2,13]

What is far from clear, however, is the degree to which sympathetic support of the normal areas of the heart compensates for local dysfunction of hypoperfused areas. Although this undoubtedly occurs in acute myocardial ischemia, the degree to which cardiac function is dependent on the sympathetic nervous system is usually unknown at the time of therapy and, therefore, the hemodynamic effects of β blockade in this setting are difficult to predict. Thus, the possibility of inducing cardiac failure is always a risk.[2,14] A related concern is the risk associated with the use of β blockers in patients with coronary artery disease during anesthesia to blunt the tachycardia and hypertension response to general surgical stimuli. These responses can provoke myocardial ischemia and infarction in such patients during surgery.[15,16] Although β blockers can control the phenomenon, the presence of β blockade may become problematic during either surgery or the postoperative recovery period, when cardiac function is usually decreased.[17]

In 1982, Zaroslinski et al[18] described the concept of ultrashort-acting β-adrenergic blockers; they envisioned a compound that is extensively and rapidly metabolized to inactive products much the same as catecholamines or nitroglycerin. Such a short-acting compound could then be administered by constant intravenous infusion to provide for controlled levels of β blockade that could be titrated and rapidly altered if

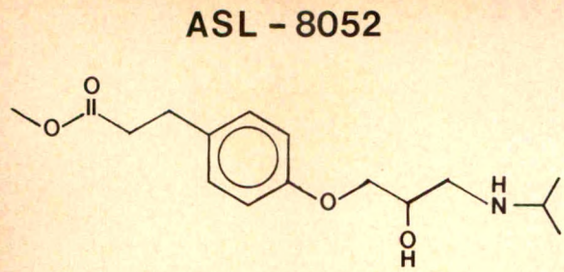

FIGURE 1. Molecular structure of esmolol (ASL-8052).

required. An ultrashort-acting β blocker was expected to be a much safer type of β blocker to use in critical care situations in which β-blocker therapy is required, such as unstable angina, acute myocardial infarction, and surgically induced tachycardia, tachyarrhythmias and hypertension. If deleterious hemodynamic effects or cardiac failure occurred as a result of β blockade with an ultrashort-acting β blocker, rapid recovery of function could be attained within minutes by simply reducing the infusion rate or ceasing administration completely.

Recent reports have outlined the molecular approaches to the design and development of ultrashort-acting β blockers.[19–22] From this work, esmolol, which is a cardioselective β blocker that possesses an extremely short duration of action, was subsequently identified[19] and characterized.[18,23–25]

Beta-Blocking Potency and Duration of Action

Esmolol (ASL-8052) (Fig. 1) is a phenoxypropanolamine, a molecular structure characteristic of conventional, second-generation β blockers. Also, esmolol contains an ester functionality in the para-position of the phenyl-ring. The presence and location of this ester are of fundamental importance in the determination of esmolol's cardioselectivity as well as its ultrashort duration of action.[19]

In initial in vitro experiments (Fig. 2), esmolol caused parallel, rightward shifts in isoproterenol concentration-response curves in guinea pig right atria and trachea.[23] The degree of rightward shift was concentration-dependent and the antagonism was always fully surmountable given sufficiently high doses of agonist. The Schild plots illustrated in Figure 3 indicate the linear relation between the concentration of esmolol and the degree of rightward shift in both tissues. The slopes of these relations did not differ significantly from 1, indicating that esmolol is indeed a β-receptor antagonist. In atria esmolol had a pA_2 of 7.0 indicating that it is about 30-fold less potent than propranolol, and about equipotent to metoprolol in this tissue. These data also indicate that esmolol was approximately 43-fold more potent at β receptors in atria than in trachea (pA_2 = 5.3).

The duration of action of esmolol was determined in barbiturate-anesthetized dogs.[23] The tachycardia and hypotension responses to a submaximal bolus dose of isoproterenol were measured before and at 10-minute intervals during and after 3 hours of continuous infusion of esmolol at different doses. Identical experiments were performed with propranolol for comparison. Esmolol caused a dose-dependent decrease in tachycardia responses. Steady-state levels of β blockade were achieved within 10 to 20 minutes of each infusion (Fig. 4). In contrast, blockade with propranolol progressively increased throughout most of the infusion period. The dose of esmolol that produced 50%

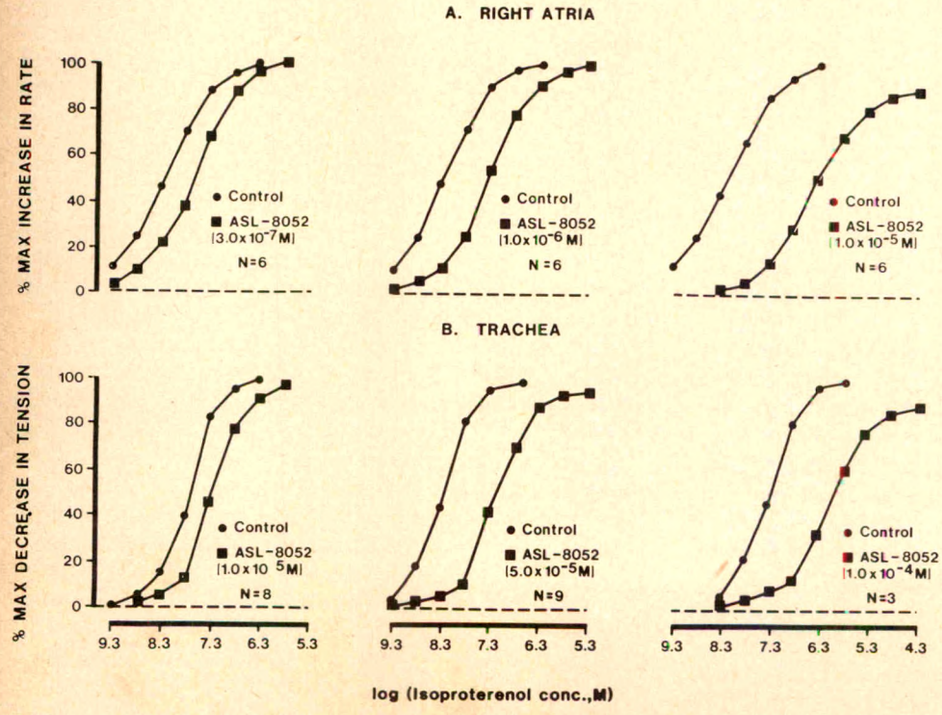

FIGURE 2. Isoproterenol concentration-response curves in **A,** isolated guinea pig right atria and **B,** trachea, in the absence and the presence of 3 concentrations of esmolol in separate experiments.

inhibition of the tachycardia response to isoproterenol was 50 μg/kg/min. After termination of the esmolol infusion, β blockade rapidly and dramatically decreased such that 20 minutes after esmolol no significant β blockade was detectable regardless of dose. This was in direct contrast to results obtained with propranolol, which indicated only minimal recovery from β blockade during the postinfusion observation period (up to 1 hour). Subsequent studies in conscious dogs, rabbits, rats and humans have confirmed that esmolol has a very short duration of action regardless of the species in which it is studied.

Although esmolol caused dose-dependent blockade of isoproterenol-induced tachycardia, it had no significant blocking effect on the hypotensive responses to isoproterenol (Fig. 5). This was in contrast to a rather dramatic blockade of isoproterenol-induced hypotension caused by propranolol. Thus, the cardioselective nature of β blockade with esmolol was clearly in evidence in this study.

The cardioselectivity of esmolol observed in vitro was further investigated in vivo using a constant flow perfused hindlimb preparation in pentobarbital-anesthetized, ganglion-blocked dogs.[13] Tachycardia and hindlimb vasodilator responses to a submaximal dose of isoproterenol were measured before and during continuous intravenous infusion of esmolol at doses that were increased at 10-minute intervals. Similar experiments were conducted with metoprolol and propranolol for comparative purposes. Esmolol caused dose-dependent blockade of isoproterenol-induced tachycardia, but produced only minimal blockade of isoproterenol-induced vasodilation (Fig. 6). These results were similar to those obtained with metoprolol, a cardioselective β blocker, but were different from those obtained with propranolol, which produced nonselective β blockade. When the effects of larger doses of esmolol were examined, blockade of vascular β receptors occurred, but equivalent levels of vascular β blockade required a dose of esmolol that was 100-fold greater than that required for cardiac β blockade. These data, therefore, confirm and extend in vitro data that initially suggested that esmolol was a cardioselective β blocker.

Ancillary Properties

Esmolol produced slight (<10%) increases in the rate of contraction of guinea pig right atria isolated from catecholamine-depleted animals at concentrations of 10^{-9} to 10^{-5} *M* (Fig. 7).[23] The compound produced a concentration-dependent depression in atrial rate at concentrations $>10^{-4}$ *M*. Esmolol had no effect on developed tension of left atria isolated from reserpinized guinea pigs at concentrations $\leq 10^{-5}$ *M*. Concentration-dependent depression in force was observed at higher concentrations.

Thus, only minimal partial agonist action was observed in isolated atria; in contrast, direct cardiac de-

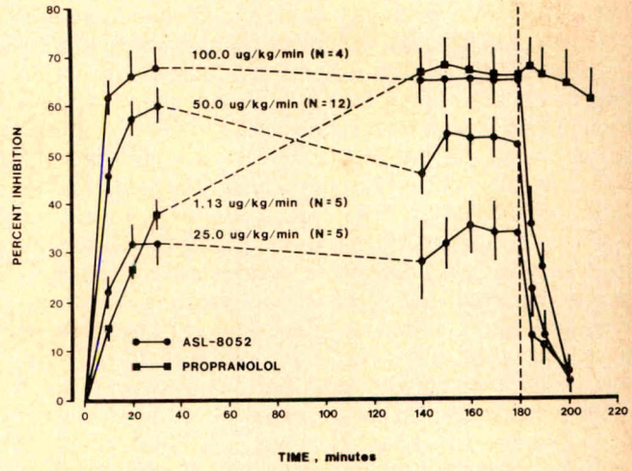

FIGURE 4. Percent inhibition of isoproterenol-induced tachycardia throughout a 3-hour constant intravenous infusion of esmolol (3 infusion rates) and propranolol, and recovery from β blockade after termination of β-blocker infusion.

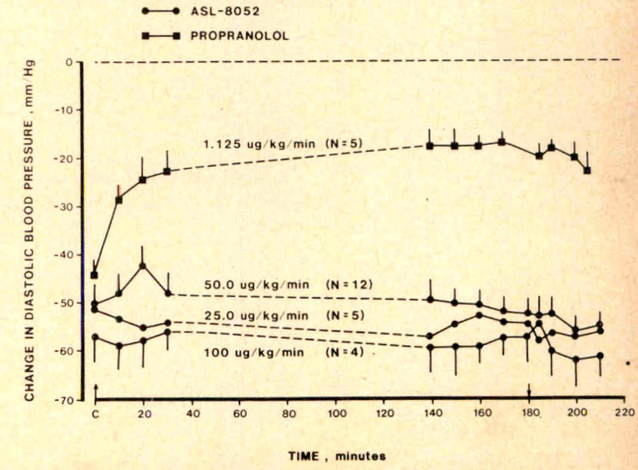

FIGURE 5. Isoproterenol-induced decreases in diastolic arterial pressure before, during and after a 3-hour constant intravenous infusion of esmolol (3 infusion rates) and propranolol. C = control response to isoproterenol in the absence of esmolol or propranolol.

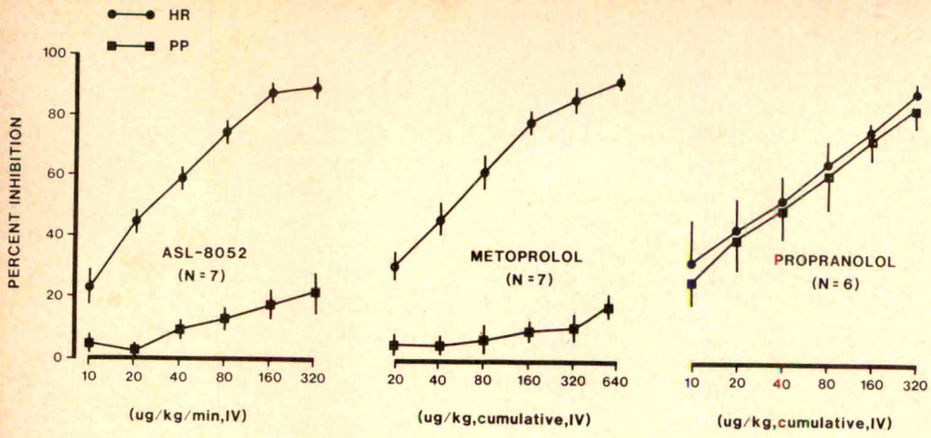

FIGURE 6. Percent inhibition of isoproterenol-induced increases in heart rate (HR) and decreases in hindlimb perfusion pressure (PP) in ganglion-blocked dogs with esmolol (**left**), metoprolol (**middle**) and propranolol (**right**), plotted as function of dose.

pression, which is a measure of myocardial membrane depression, occurred only at very high concentrations with esmolol. This latter finding suggests that esmolol possesses only slight membrane-depressant action and this has been confirmed by other related studies. Esmolol had no effect on conduction in the frog sciatic nerve at concentrations ≥ 0.1 *M* and did not affect corneal sensitivity in conscious rabbits at similar concentrations.

To examine further the direct effects of esmolol on cardiac tissue, studies were conducted in catecholamine-depleted, anesthetized dogs pretreated with reserpine.[24] Esmolol had no effect on heart rate, arterial blood pressure, left ventricular (LV) dP/dt or right ventricular contractile force at an intravenous dose of ≤ 500 μg/kg/min. Higher doses produced dose-dependent decreases in heart rate, arterial blood pressure and contractility and increases in LV end-diastolic pressure (EDP). These effects are likely a result of direct membrane depression and are characteristic of high doses of many β blockers. Of particular interest, however, is that in contrast to long-acting β blockers, direct cardiac depression with esmolol is rapidly reversible, as shown in Figure 8. In the dog whose data are shown in this figure, esmolol was infused at ascending dosages of 300 to 3,800 μg/kg/min at 10-minute intervals. At the end of the highest infusion rate, mean arterial pressure was approximately 15 mm Hg, contractility was severely depressed and LVEDP was dramatically increased. Cardiovascular recovery began within 1 minute after termination of esmolol infusion; essentially complete recovery occurred in approximately 10 minutes. Thus, although direct cardiovascular depression can be seen at extremely large doses of esmolol that would never be used clinically, the ultrashort duration of action of the compound provides a reassuring margin of safety in the event of an overdose.

Hemodynamic Effects of Esmolol

Brief intravenous infusions of esmolol (20 minutes) at doses of 5 to 160 μg/kg/min had no effect on arterial pressure, LVEDP, cardiac output, heart rate or peripheral vascular resistance in chronically instrumented, trained, conscious dogs (Figs. 9 and 10). Esmolol, however, produced a dose-dependent decrease in maximal LV dP/dt (23% at the largest dose), which fully recovered by 20 minutes after completion of the highest infusion rate of esmolol. Qualitatively similar effects were observed with short intravenous infusions of metoprolol and propranolol in the same experimental animals using doses that produced similar degrees of β blockade; however, propranolol and metoprolol in larger doses also decreased cardiac output and increased peripheral vascular resistance by about 30%. Propranolol also caused a small decrease in heart rate at larger doses.

In contrast to results with esmolol, however, the hemodynamic and electrocardiographic effects of metoprolol and propranolol were not diminished 20 minutes after administration of the largest dose. These data suggest that although esmolol lowered LV dP/dt in a dose-dependent fashion, as did propranolol and metoprolol, this effect did not influence cardiac output, whereas cardiac output decreased with the standard β blockers. Unlike propranolol and large doses of metoprolol, esmolol did not increase peripheral vascular resistance.

In pentobarbital-anesthetized, vagotomized dogs, esmolol produced more marked hemodynamic changes than were seen in conscious dogs.[24] Thus, esmolol (5 to 160 μg/kg/min) produced dose-dependent decreases in heart rate, LV dP/dt and right ventricular contractile force, which amounted to 15%, 35% and 35% reductions, respectively, with the largest dose tested. Esmolol also produced a very small decrease in diastolic blood pressure, which at maximum for this dose range averaged <10%. When autonomic tone was eliminated in these dogs by ganglion blockade, the same doses of esmolol did not significantly affect these variables.

The direct vascular effects of esmolol were examined in constant flow perfused hindlimbs of pentobarbital-anesthetized, ganglion-blocked dogs. Esmolol had no effect on hindlimb perfusion pressure at intravenous doses up to and including 1,280 μg/kg/min

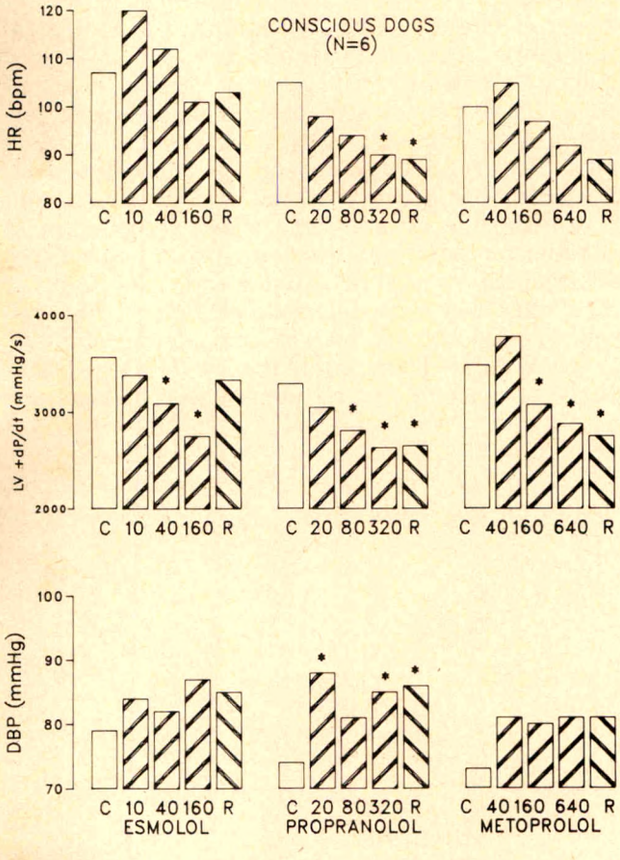

FIGURE 9. Hemodynamic effects of esmolol, propranolol and metoprolol in trained, chronically instrumented, conscious dogs. Number beneath columns refers to doses administered, expressed as μg/kg/min for esmolol and μg/kg, cumulative, for propranolol and metoprolol. * $p < 0.05$ vs control. C = predrug control value and R = value after 20 minutes of recovery, after infusion of each drug. DBP = diastolic blood pressure; HR = heart rate.

TABLE I Effect of Esmolol on Hindlimb Perfusion Pressure Responses to Norepinephrine in Ganglion-Blocked, Propranolol-Treated Dogs (n = 4)

Norepinephrine Dose (ng/kg, i.a.)	Hindlimb Perfusion Pressure (mm Hg)		
	28	56	112
Control	31 ± 8	40 ± 8	58 ± 9
Esmolol*			
100	31 ± 8	41 ± 8	59 ± 9
200	33 ± 8	44 ± 9	62 ± 9
400	35 ± 7	44 ± 9	62 ± 8

Data are mean ± standard error of the mean.
* In μg/g/min, intravenously.
i.a. = intraarterial.

(Fig. 11). It induced slight vasoconstriction upon close intraarterial infusion over the range of 45 to 360 μg/kg/min. The maximal increase in perfusion pressure observed with intraarterial dosing was 19 ± 6 mm Hg at a dose of 180 μg/kg/min. These results indicate that esmolol is devoid of direct vascular action at dosages that are within or above the β-blocking dosage range, but suggest that extremely large dosages may cause vasoconstriction.

To investigate the possibility that esmolol may possess some degree of α-adrenergic blocking action, hindlimb vasoconstriction responses to norepinephrine were examined before and during infusion of esmolol at increasing doses.[23] Esmolol did not modify the norepinephrine dose-response curve (Table I). Also, the drug did not modify hindlimb vasoconstrictor responses elicited by stimulation of the ipsilateral sympathetic chain (Fig. 12). In these studies in the neurally intact hindlimb, esmolol had a tendency to produce vasoconstriction, although this was not statistically significant. Thus, esmolol does not interfere with peripheral sympathetic nerve function, is not a vasodilator and does not produce α blockade in the canine hindlimb.

The effects of esmolol on cardiac hemodynamics, coronary blood flow and myocardial oxygen consumption were also studied.[24] Esmolol at 310 μg/kg/min produced significant decreases in heart rate and LV dP/dt but had no effect on arterial blood pressure or myocardial oxygen extraction (Fig. 13). Esmolol reduced myocardial oxygen consumption and slightly increased coronary vascular resistance. Esmolol also completely eliminated cardiostimulation in response to isoproterenol. These effects are well-known characteristics of β blockade and form the basis for the use of these agents for the treatment of ischemic heart disease.

Electrophysiologic effects of esmolol: The effects of esmolol on cardiac transmembrane potential were examined in vitro using a variety of different cardiac tissues and conventional microelectrode techniques. Esmolol had no effect on the frequency or character of spontaneous activity in the isolated rabbit sinus node, nor did it alter the action potentials of AV nodal cells at concentrations of $\leq 10^{-5}$ *M*.

The effects of norepinephrine on sinus rate and AV nodal conduction, however, were blocked by esmolol at concentrations of 10^{-7} to 10^{-5} *M*. The compound also blocked triggered activity induced by norepinephrine in canine atrial fibers within the same concentration range. In canine Purkinje fibers, esmolol at 10^{-7} and 10^{-6} *M* slightly increased resting membrane potential, perhaps indicative of the small degree of partial agonist activity previously observed in isolated atria. The drug had no effect on other measures of the Purkinje fiber action potential at concentrations of $\leq 10^{-5}$ *M*. Higher concentrations produced a decrease in action potential amplitude, maximum rate of depolarization and action potential duration indicative of membrane depression. Esmolol also blocked norepinephrine-induced automaticity and slow responses in canine Purkinje fibers within the lower concentration range. These results are characteristic of β blockers in

general and indicate that esmolol lacks direct, pharmacologically significant electrophysiologic effects at reasonable β-blocking concentrations.

The effects of esmolol on intracardiac conduction in intact hearts was studied in pentobarbital-anesthetized, open-chest dogs instrumented for recording of right atrial, right ventricular and His bundle electrograms. Conduction intervals, sinus node recovery time and AV nodal refractory periods were measured before and during constant intravenous infusion of esmolol at 310 μg/kg/min. The AV nodal Wenckebach cycle length was also determined during incremental atrial pacing. At the basic cycle length of 300 ms, esmolol significantly lengthened the sinus node recovery time and the A-H conduction interval (Table II). The H-V interval, however, was not affected by the drug. These changes were also associated with significant increases in the relative and functional refractory periods and AV nodal Wenckebach cycle length during esmolol infusion. These observations are characteristic of β blockers and form the basis for their use in controlling elevated ventricular rate resulting from supraventricular tachycardia or for interruption of reentrant pathways involving the AV node. Esmolol-induced slowing of AV conduction and increased AV refractoriness are likely a result of inhibition of sympathetic tone in these animals, because in vitro the drug had no direct effect on the AV node at β-blocking concentrations.

Effects of esmolol on manifestations of myocardial ischemia: Intravenous infusion of esmolol at 150 μg/kg/min in anesthetized dogs decreased the incidence of spontaneous ventricular fibrillation induced by abrupt occlusion of the left anterior descending and anterior septal coronary arteries (Table III). In this study, esmolol decreased heart rate but had no significant effect on mean arterial blood pressure.

Pharmacodynamics and pharmacokinetics of esmolol: Because the concept of ultrashort-acting β blockers reflects a pharmacokinetic departure from conventional agents and because the primary use of an ultrashort-acting β blocker is to enable titratable β blockade, the pharmacokinetic and pharmacodynamic characteristics of esmolol are of singular importance. These properties were characterized in anesthetized dogs in which blood levels of esmolol were determined by either gas chromatographic methods or use of carbon-14-labeled compound. Both methods require im-

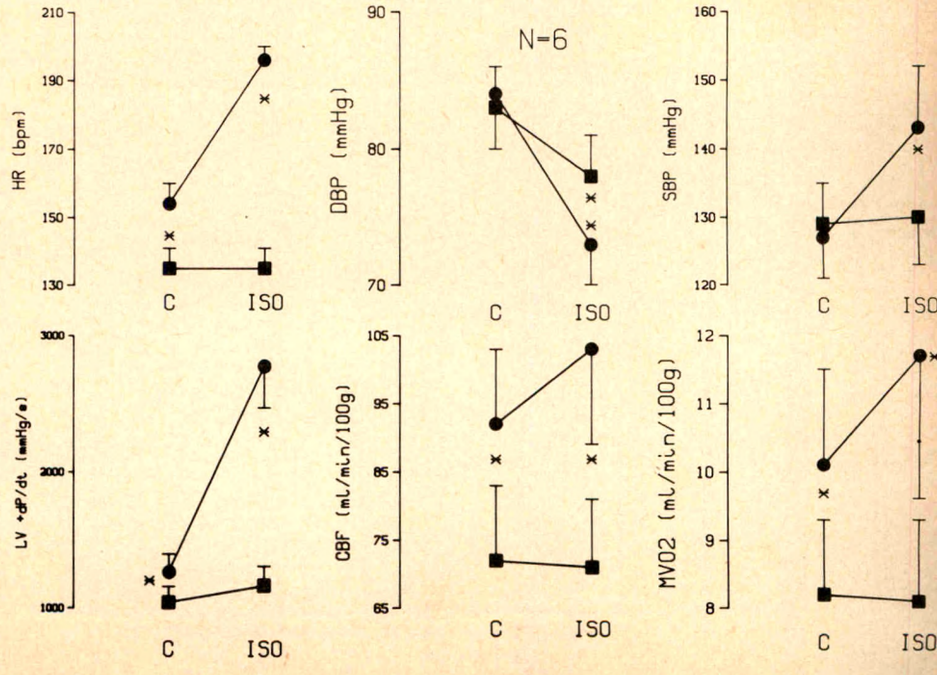

FIGURE 13. Effects of esmolol (310 μg/kg/min) on hemodynamics, coronary blood flow (CBF) and myocardial oxygen consumption (MVO_2). Asterisk above C indicates that esmolol significantly ($p < 0.05$) reduced the variable. The effect of isoproterenol (ISO) infusion (0.25 μg/kg/min for 10 minutes) on these variables was also measured in the absence and presence of esmolol. Asterisk above ISO indicates a significant change in the variable by isoproterenol at the $p < 0.05$ level vs control. DBP = diastolic blood pressure; HR = heart rate; SBP = systolic blood pressure; ● = saline; ■ = esmolol.

TABLE IV Effect of Plasma on Red Blood Cell (RBC) Esmolol Esterase Activity in Dog Blood

mediate esterase inhibition because of the rapid metabolism of esmolol in blood and subsequent separation of esmolol from its primary acid metabolite using accepted analytic techniques.

Two independent studies in dogs have shown excellent correlation between the time course and degree of β blockade and the esmolol concentration in blood. In 1 study,[26] esmolol was infused at 3 dosages, each maintained for 1 hour. The degree of β blockade was tested at 10-minute intervals. Steady-state levels of β blockade were rapidly induced by esmolol infusion and the degree of blockade was dose-dependent. Also, β blockade rapidly decayed after esmolol infusion ended. These effects closely followed the blood levels of esmolol. Thus, steady-state levels of esmolol were quickly established and closely followed the infusion rates. Also, the esmolol blood levels rapidly declined after the end of infusion in parallel with the degree of β blockade. An excellent linear relation between the log of the steady-state blood level of esmolol and the degree of β blockade was observed. The average concentration of esmolol, which produced 50% inhibition of isoproterenol-induced tachycardia, was 185 ± 40 ng/ml in this study.

An additional study examined more closely the onset characteristics of β blockade with esmolol.[27] In this study a 500 μg/kg/min loading dose of esmolol was administered for 1 minute followed by a maintenance infusion at varying doses. To examine the onset of β blockade on a moment-to-moment basis, a constant intravenous infusion of isoproterenol was used to provide a continuous stimulation of β receptors. Figure 14 shows the time course of both β blockade and the esmolol blood level during and after 3 infusions of esmolol. The onset of β blockade was extremely rapid, following within seconds of initiation of esmolol administration. Peak blockade occurred within 5 minutes at each dose. Good correlation between the level of esmolol and the degree of blockade was achieved except at the earliest time, at which the degree of blockade lagged behind the blood levels of the drug, which were changing rapidly during this period. There was excellent correlation between the decay of blood levels postinfusion and the decay of β blockade in these experiments. In both this study and the previously described studies, the postinfusion esmolol concentration decayed with a disappearance half-life of approximately 10 minutes.

The pharmacokinetic profile of esmolol was determined in conscious dogs after a single intravenous bolus of 10 mg/kg and after a continuous intravenous infusion of 200 μg/kg/min for 2 hours.[28] The key pharmacokinetic parameters of esmolol were similar after bolus and intravenous infusions. A rapid decrease in the esmolol blood concentration occurred, in part as a result of distribution from blood to tissue but, more importantly, due to rapid metabolism of the com-

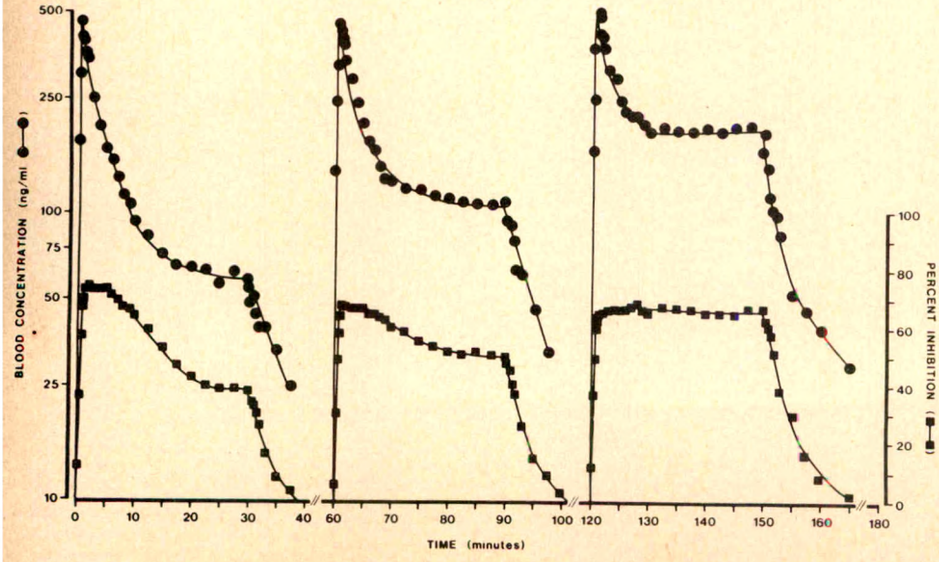

FIGURE 14. Relation between the time course and magnitude of β blockade and the change in blood concentrations of esmolol during and after infusion of esmolol. Percent inhibition refers to the inhibition of isoproterenol-induced tachycardia. Esmolol doses were 12.5, 25 and 50 μg/kg/min, each preceded by a loading dose of 500 μg/kg/min.

pound by blood esterases during transport through the vascular bed. The latter conclusion is supported by the finding that the total body clearance of esmolol (350 ml/kg/min) is greater than resting cardiac output in dogs.

Metabolism of esmolol: The major pathway of esmolol metabolism is hydrolysis of the methyl ester, resulting in methanol and the primary acid metabolite, ASL-8123.[29] Although the metabolite can be shown to produce β blockade, it possesses extremely low affinity for β receptors, with a pA_2 of 3.8. Thus, ASL-8123 is 1,500-fold less potent than esmolol.

Metabolism of esmolol takes place rapidly and extensively in whole blood, and in both dog and human blood the esterase is located in red blood cell cytosol. Unlike most therapeutic agents containing esters, esmolol is totally unaffected by plasma cholinesterase. Under standard in vitro conditions the half-life of esmolol in dog and human whole blood was 12.5 and 27.1 minutes, respectively. For full enzymatic activity the esmolol esterase in red blood cell cytosol requires a heat labile, high-molecular-weight plasma component (Table IV). Washed red cells from dogs contain only half of the original activity of whole blood. Activity is restored by re-addition of plasma or a high-molecular-weight plasma fraction. The enzyme is not inhibited to any significant degree by cholinesterase inhibitors such as physostigmine or echothiophate, but is totally inhibited by sodium fluoride.

No metabolic interactions have been observed between esmolol and other ester-containing molecules of clinical relevance. These findings are consistent with esmolol being metabolized by a blood esterase different from these agents. Also, in anesthetized dogs, esmolol infusion of 100, 300 and 500 μg/kg/min did not modify the magnitude or duration of neuromuscular blockade in response to succinylcholine.

Discussion

Dr. Reves (Durham, North Carolina): I was intrigued with your intact dog data that showed dose-dependent effects in left ventricular dP/dt, right heart contractile force and heart rate. It seemed to me that in decreases in contractility, the slope was steeper than with heart rate, which is what we have seen, too. How does this compare with other drugs, and do you think this is more of a negative inotrope drug than a negative chronotrope?

Dr. Gorczynski (McGaw Park, Illinois): I do not know for sure; the contractility decreases are confounded by the fact that heart rate also decreases. A proper comparison would be to compare the slopes when you pace the animals—comparing the slope of dP/dt under pacing conditions with the slope of heart rate. I think two things are going on: a decrease in heart rate, which by itself is probably going to decrease contractility (i.e., negative staircase), and then there is the added effect of esmolol on top of that.

Dr. Reves: But how does esmolol compare with something like propranolol?

Dr. Gorczynski: They are very similar, in our hands at least.

Dr. Reves: The slopes look the same?

Dr. Gorczynski: Yes.

Dr. Sonnenblick (Bronx, New York): I think one thing ought to be clarified. In terms of reducing contractility, how directly toxic is the drug to the myocardium? In your findings, there was very little evidence of it. On the other hand, the clinical state of the animal and his level of catecholamines is going to be secondary, which is withdrawal of catecholamines—which is not a direct depression of the heart. Just by withdrawing catecholamines, the heart rate usually will be more affected than the contractility. In most β-blocker preparations, you can lower heart rate with small amounts of β blockade, and then it takes more drug to produce decreases in contractility. I am not sure why one necessarily has to have a parallel between the two.

Dr. Morganroth (Philadelphia, Pennsylvania): Dr. Sonnenblick, how would you go about comparing esmolol with a drug such as propranolol in terms of direct negative inotropic effect? In our supraventricular tachycardia data, esmolol had a more profound effect on blood pressure than propranolol, which, of course, has some theoretical benefits in a postoperative cardiac surgery patient. But the question is whether there is a way to isolate, in a model, the negative inotropic effects in a comparative manner.

Dr. Sonnenblick: In the absence of catecholamines, looking at the tissue directly reveals no difference. But once you have rapid tachycardia with a high catecholamine state, the clinical response is not just in the myocardium, and the blood pressure is usually not a function of contractility, unless the cardiac output is very limited. I think you may be looking at separate effects. I would not equate blood pressure with contractility.

Dr. Morganroth: Therefore, the differential effects will show later, and apparently with esmolol the differences may just be due to an unbalanced group in terms of homogeneity of these factors.

Dr. Gorczynski: Keep in mind also that when you compare esmolol with propranolol, it is like comparing apples and oranges. Reflex vasoconstriction is always greater in the presence of propranolol than it is in the presence of a very cardioselective β blocker.

Dr. Sonnenblick: I think another thing that will come out in the clinical pharmacology section is that all the β blockers will drop cardiac output acutely. The vascular responses to that in the periphery can be somewhat complex, but that does not directly mean that the myocardium is depressed; I think this points out that it may be a separate issue.

Dr. Gray (Los Angeles, California): You have shown that the half-life is very short and the clearance rate is very rapid. Most of your experiments appear to be over a relatively short period of infusion. I think there was one where you went up to 200 minutes. Have you any experience with longer infusions, or any reason to believe that if you have longer infusions, there would be a different metabolic clearance rate or different duration of action?

Dr. Gorczynski: Yes, we have given it for up to 5 hours to determine pharmacologic effects and found a very short half-life. We have also, in our toxicity studies, gone up to 14 days of continuous administration and found blood levels fall just as rapidly.

Dr. Gray: This is in the intact dog?

Dr. Gorczynski: Yes. Conscious dogs.

Dr. Morganroth: You should not necessarily limit esmolol to patients with ischemic heart disease because the use of β blockers in patients with cardiomyopathy is an interesting problem. This may be an ideal agent to screen patients for those who may do well with β blockade in general idiopathic cardiomyopathy.

Dr. Sonnenblick: Absolutely.

Dr. Kirshenbaum (Boston, Massachusetts): We tried to answer that question. Every patient in the ischemic study—with acute infarct or unstable angina—who tolerated esmolol was able to go on to an oral β blocker and tolerate that with roughly equivalent heart rate reductions. It is hard to say exactly equivalent, because the clinical situation in the acute ischemic episode versus several days later obviously changes. The other way around is the fact that some patients failed to tolerate esmolol when they were acutely ill. We did not predict that they would not tolerate an oral long-acting β blocker several days down the line, but, again, their

clinical hemodynamic state was very different 3 or 4 days later. We found it very convenient that if a patient tolerates esmolol, we were very comfortable about starting a long-acting cardioselective β blocker, without concern over precipitating significant failure or hypotension.

Dr. Iskandrian (Philadelphia, Pennsylvania): I think it is very important for clinical research to determine that answer. There are many patients in that group and they are facing cost containment pressures plus the hesitation about surgery in such patients. Many are resorting to β blockers for them, and it would be convenient to be able to tell the physician in a couple of hours: Yes, your patient would tolerate x amount of drug if he can tolerate the infusion of a very short-acting β blocker.

Dr. Gorczynski: The only problem with this approach is that showing that someone can tolerate β blockade with esmolol at one point in time really does not have strong predictive value in estimating what that patient can tolerate at another point in time if autonomic conditions are changing, such as in acute myocardial infarction.

Clinical Pharmacology, Pharmacodynamics and Interactions with Esmolol

DAVID T. LOWENTHAL, MD, R. STEPHEN PORTER, PharmD, STEVEN D. SARIS, MD, CAROL M. BIES, RN, MARY BETH SLEGOWSKI, BS, and ALLISON STAUDACHER, MT, ASCP

The clinical pharmacology and pharmacodynamic data from several clinical trials are summarized. The pharmacokinetic profile of esmolol alone and in the presence of digoxin, morphine and warfarin was studied. Conversely the effect of esmolol on these drugs was monitored. No clinically important effects were observed on vital signs, blood chemistry or hematology. The pharmacokinetic interactions associated with administration of these drug combinations were statistically significant in several cases, but they were not considered to be of clinical importance. (Am J Cardiol 1985;56:14F–18F)

Esmolol HCl is an ultrashort-acting, cardioselective β-adrenergic blocking agent proposed for use in the therapy of supraventricular tachyarrhythmias, perioperative tachycardia and hypertension, postoperative hypertension and acute myocardial ischemia.[1] Esmolol's short half-life (approximately 9 minutes) provides an element of safety in treating critically ill patients that is not present in currently available β-blocking agents. In animals esmolol has been shown to have 1/40 of the β-blocking potency of propranolol.[2] Esmolol demonstrated no intrinsic sympathomimetic activity in animals and no significant membrane stabilizing activity at therapeutic dosages. Esmolol inhibits the β_1 receptors located chiefly in cardiac muscle, but at 40- to 100-fold higher doses it also inhibits β_2 receptors located chiefly in the bronchial and vascular musculature, respectively. This report summarizes the clinical pharmacology data of esmolol from several studies.

Metabolism and Pharmacokinetics

Esmolol is metabolized by esterases that are located in red blood cells and not by plasma cholinesterases.[3] The hydrolysis of the esmolol ester results in the formation of an acid metabolite (ASL-8123 or 3-[4-(2-hydroxy-3-(isopropylamino)propoxy)-phenyl]propionic acid) and methanol. In vitro and in vivo animal studies have shown that the acid metabolite is only 1/320 as potent as esmolol as a β-adrenergic blocking agent. Methanol blood levels, monitored in subjects receiving esmolol for 6 hours at 300 μg/kg/min and 24 hours at 150 μg/kg/min, were usually within endogenous levels and always at least 2 orders of magnitude below levels associated with methanol toxicity.[1]

The fact that esmolol metabolism is based in the vascular system makes it inherent that its metabolism is both rapid and complete. Less than 2% of the drug is excreted unchanged in the urine. Within 24 hours of discontinuation of infusion, 73 to 88% of the dosage has been accounted for in the urine as the acid metabolite of esmolol. Also consistent with the rapid metabolism of esmolol is the finding that it is only moderately protein bound (55% to human plasma protein). The acid metabolite has an even weaker affinity for protein (10% binding to human plasma protein).

Esmolol has been used clinically in the range of 25 to 300 μg/kg/min. Blood levels obtained and pharmacokinetic parameters calculated therefrom have been found to be linear in this dosage range. Esmolol has a rapid distribution half-life of about 2 minutes and a short elimination half-life of about 9 minutes.[4] The total body clearance of esmolol reflects these short half-lives. Total body clearance in man was found to be approximately 20 liters/kg/hr. Since this is about 3 times greater than cardiac output, the metabolism of esmolol is obviously not limited by the rate of blood flow to metabolizing tissues such as the liver. This is consistent with the data showing that erythrocyte esterases are responsible for the hydrolysis of esmolol.

The kinetics of the acid metabolite have also been shown to be linear over the dose ranges studied. The elimination half-life of this metabolite is about 3.7 hours while the total body clearance is approximately equivalent to the glomerular filtration rate.[4]

Because of esmolol's rapid clearance and short half-life, it can be easily titrated to either increased or de-

creased blood levels within minutes. Using a loading dose, steady-state blood levels of esmolol for dosages of 50 to 300 μg/kg/min were obtained within 5 minutes.[4,5] As previously stated these levels are linearly related to the dose administered over this dosage range. Equally striking is the fact that blood levels of esmolol are not detected approximately 30 minutes after discontinuation of the infusion. Ten to 20 minutes after discontinuation of esmolol infusion substantial recovery from the β blockade is routinely seen in patients.

Pharmacodynamic Studies with Esmolol

Clinical pharmacology studies in normal volunteers confirm the β-blocking activity of esmolol; they show reduction in heart rate at rest and during exercise and inhibition of isoproterenol-induced increases in systolic blood pressure, decreases in diastolic blood pressure and increases in heart rate.[6,7]

The relative cardioselectivity of esmolol was demonstrated in patients with asthma and in patients with chronic obstructive pulmonary disease (COPD).[8] In asthmatic patients, esmolol, 300 μg/kg/min, produced a slight decrease in specific airway resistance and slightly increased the sensitivity to induced bronchoconstriction. These effects were not clinically significant, and esmolol was well tolerated by these patients. No patients were discontinued from the study. Six of the patients also received intravenous propranolol and, at 1 mg, 2 of them experienced significant symptomatic bronchospasm requiring bronchodilator treatment. In addition, propranolol induced bronchospasm in 1 patient at the 5-mg dose. In approximately 60 patients with COPD, no adverse pulmonary effects were observed during clinical studies of esmolol for treatment of supraventricular tachycardia or in perioperative settings.

In a small study in patients with acute ischemic heart disease (unstable angina pectoris or acute myocardial infarction), esmolol, 300 μg/kg/min, decreased cardiac index and systemic vascular resistance but did not affect left ventricular filling pressure. Cardiac index returned to baseline levels during continued maintenance infusions of esmolol; systemic vascular resistance returned to baseline levels within 30 minutes after infusion.

In a trial using patients with chronic atrial fibrillation,[9] esmolol produced a significant dose-dependent decrease in ventricular rate. A dose correlation was observed between blood concentration of esmolol and reductions in heart rate. Furthermore, blood levels of the acid metabolite were found for some time after discontinuation of esmolol infusion and disappearance of esmolol blood levels, but were not associated with β blockade.

Finally, esmolol, when infused in the dose range of 100, 200 or 300 μg/kg/min, effectively attenuated tachycardia and increases in the rate-pressure product induced by endotracheal intubation compared with placebo. The response was dose-related.[10]

Study Design

To study possible drug interactions, clinical trials were conducted in which digoxin,[7] morphine[11] and warfarin[11] were coadministered with esmolol. All drugs were studied in healthy normal male volunteers. Each study consisted of 3 study periods: esmolol alone, second drug alone and esmolol in combination with the second drug. The pharmacokinetics of each drug were monitored as a sensitive indicator of any changes occurring during concomitant therapy. Thus, the pharmacokinetics of digoxin, morphine and warfarin were evaluated alone and in the presence of esmolol; furthermore, esmolol was evaluated alone and in the presence of digoxin, morphine or warfarin. Comparisons were then made between periods of treatment to detect differences resulting from concomitant therapy. Digoxin, warfarin and esmolol were studied under steady-state conditions. Morphine was studied after a single intravenous bolus.

Studies were carried out at the clinical research unit of Hahnemann University. These were all open-label studies approved by institutional review committees and written informed consent was obtained from all volunteers. All subjects were screened to ensure that they were healthy and that their prestudy laboratory parameters were within normal ranges.

Results and Discussion

Esmolol-digoxin interaction: Interactions with digoxin were studied in 12 normal male subjects.[7] The pharmacokinetics of esmolol alone, during and after a 6-hour infusion (300 μg/kg/min) and the pharmacokinetics of digoxin alone (administered to obtain blood levels of 0.8 to 2 ng/ml) at steady state were compared with the same conditions but administered concurrently. The steady-state blood levels, total body clearance, half-lives and volume of distribution for esmolol did not show any significant changes between esmolol and esmolol-digoxin treatments. The mean concentrations for esmolol during the 2 treatments are shown in Figure 1. Additionally, no significant changes in half-lives or maximal blood levels of the acid metabolite of esmolol were seen between esmolol and esmolol-digoxin treatments. The mean concentrations for the

FIGURE 1. Mean esmolol blood levels in 11 normal subjects are shown when esmolol was given alone (■) and in the presence of steady-state levels of digoxin (●). Esmolol infusion was initiated with a titration period and maintained at 300 μg/kg/min for 6 hours.

acid metabolite of esmolol during the 2 treatments are shown in Figure 2. A slight influence of esmolol was seen on digoxin concentrations at 4 hours after dosing, as shown in Figure 3. Serum digoxin levels were increased by 9.6 to 19.2% during esmolol-digoxin treatment compared with digoxin alone. However, only the 4-hour digoxin serum levels were significantly elevated when the 2 treatments were compared by subject. Two- and 6-hour samples did not show any significant differences. The total area under the digoxin-concentrations-versus-time curve during the 6-hour esmolol infusion was significantly higher in the presence of esmolol than when digoxin was given alone. No significant change in peak digoxin levels was observed. The changes in digoxin pharmacokinetics are not considered to be of a clinically significant magnitude. However, caution should be exercised in using the drugs in combination because digoxin levels may be slightly elevated during esmolol infusion.

FIGURE 3. Mean digoxin levels in 11 normal subjects are shown when digoxin was given alone (■) and in the presence of esmolol (●); esmolol infusion lasted 6 hours. Digoxin had been given to a steady-state therapeutic level before the study period shown in this figure.

Esmolol-morphine interaction: The interactions between morphine and esmolol were studied in a similar trial. Ten normal men were infused with esmolol alone for 4 hours (300 μg/kg/min). The next day each received a slow injection of morphine sulfate (3 mg) and on the third day similar doses of morphine and esmolol were coadministered. The pharmacokinetics of esmolol and morphine alone were compared with the pharmacokinetics of the 2 drugs when they were coadministered.

Steady-state blood levels of esmolol during coadministration of morphine were generally higher (9 of 10 subjects) than during esmolol treatment alone. However, because of the variability in the individual blood level determinations only 2 of the 10 subjects showed statistically significant increases in steady-state esmolol levels. As shown in Figure 4, the mean steady-state

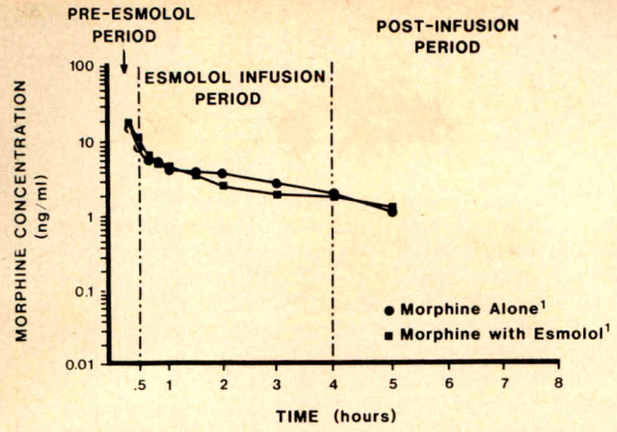
FIGURE 5. Mean blood levels of the acid metabolite of esmolol (ASL-8123) in 10 normal subjects are shown when esmolol was given alone (■) and in the presence of steady-state levels of morphine (●). Esmolol infusion was initiated with a titration period and maintained at 300 μg/kg/min for 4 hours.



1. Mean of 10 subjects.

FIGURE 6. Mean morphine levels in 10 normal subjects are shown when morphine was given alone (●) and in the presence of esmolol (■); esmolol infusion lasted 4 hours. Morphine had been given to a steady-state therapeutic level before the study period shown in this figure. Morphine was studied after single intravenous infusion of morphine sulfate.

blood level of esmolol was significantly higher (46%, $p < 0.05$) during the morphine-esmolol period. Morphine, however, had no effect on the half-life of esmolol. It also had no effect on the blood levels, total body clearance, elimination rate constant and terminal elimination half-life of the acid metabolite of esmolol. A plot of mean concentrations for the acid metabolite in all subjects is summarized in Figure 5.

Morphine serum levels were similar during both morphine and morphine-esmolol treatment periods. Thus, neither esmolol nor its acid metabolite had any effect on the area under the concentration-time curve or the elimination half-life of morphine. The mean morphine levels are shown in Figure 6.

Based on the results of this study, esmolol caused no changes in the pharmacokinetics of morphine. Morphine had no effect on the pharmacokinetics of the acid metabolite of esmolol. Morphine, however, may increase steady-state blood levels of esmolol. Although caution should be exercised when administering esmolol and morphine simultaneously, the short half-life of esmolol will allow rapid titration of steady-state levels of esmolol by changes in the infusion rate.

Esmolol-warfarin interaction: Preliminary data of a similar interaction study between esmolol and warfarin in normal men showed that the concomitant administration of esmolol and warfarin does not influence warfarin plasma levels. There are no differences in area under the curve, Cmax (maximum plasma concentration) and Tmax (time to reach Cmax) when comparing warfarin with warfarin plus esmolol. Esmolol concentrations are equivocally higher when given with warfarin.

The studies with digoxin, morphine and warfarin show that they are well tolerated when administered alone and in the presence of steady-state levels of esmolol.

In summary, esmolol is well tolerated when given in the presence of digoxin, morphine or warfarin. Conversely these drugs were also shown to be well tolerated when given in the presence of steady-state levels of esmolol (300 μg/kg/min dose). No clinically important effects were observed on vital signs, blood chemistry or hematology. The pharmacokinetic interactions associated with administration of these drug combinations were statistically significant in several cases but they are not considered to be of clinical importance. In view of the results of these interaction studies, esmolol should be administered cautiously to patients being treated concurrently with digoxin, morphine or warfarin. However, the short half-life enhances the safety of esmolol use because it allows rapid alteration of blood esmolol levels by changing its infusion rate.

Discussion

Dr. Sonnenblick (Bronx, New York): The one thing about esmolol that does seem a bit different from the usual β blockers is the extent of the fall in blood pressure, which one would not predict in the usual β response in which there is a fall in cardiac output, an increase in resistance and very little change in blood pressure. What were the ranges of the change in blood pressure and, although on the average they were tolerated, were they tolerated individually?

Dr. Lowenthal (Philadelphia, Pennsylvania): They were tolerated in the total group. Interestingly, in normal volunteers during the drug interaction studies, there was hardly any significant change at all in blood pressure, and even less change in heart rate. There were times when we thought we were giving saline or placebo because we clearly did not see any pharmacodynamic effect.

Dr. Iskandrian (Philadelphia, Pennsylvania): Dr. Lowenthal, why were these 3 drugs chosen to study for interactions? I ask that because in that clinical setting I can think of more commonly used drugs, such as nitrates, dopamine, dobutamine and heparin, rather than warfarin, morphine or digoxin.

Dr. Lowenthal: That is a very valid point. Patients who are admitted to a coronary care unit with myocardial infarction and chest pain are frequently given morphine. This was a study to try and mime a true clinical setting in which esmolol might be given to such a patient, who is also on morphine. If esmolol caused a higher availability of morphine in a myocardial infarction setting, the results of future research with myocardial infarction patients may be clouded because of esmolol's effect on blood levels of morphine. This interaction study was done to prepare for esmolol studies in patients with myocardial infarction. Digoxin was studied because many patients who will receive esmolol will also be given digoxin, and the therapeutic window of digoxin is known to be very narrow. We tested warfarin because there are a number of patients who are on anticoagulant therapy. Because warfarin is a highly protein-bound drug, it was tested as a representative of the highly protein-bound class of drugs. Many drug interactions are a direct result of altered protein binding.

Dr. Sonnenblick: Just for the record, I would like Dr. Lowenthal to clarify one thing. In a person without a compromised circulation and with a normal heart rate, what are the limits to how far the drug has been given, and are there any other cardiovascular effects to be seen? You were saying that there was no change in blood pressure and that heart rate at rest does not change. Is that really the result?

Dr. Lowenthal: Yes, when we gave esmolol up to 300 μg/kg/min to normal volunteers, no changes were seen in heart rate and only small changes in blood pressure. The other thing that has not been done, and I have discussed this issue with other investigators, is to really see whether there is β blockade in these normal volunteers. This could be done simply by giving an isoproterenol challenge or administering some exercise studies.

Dr. Gray (Los Angeles, California): First a comment, then some questions. I think the diversity of responses that you are alluding to, and which I believe that we can attest to in our clinical setting, may, in fact, relate to something that Dr. Sonnenblick mentioned. That is, the response to this drug and other β blockers must be very dependent on catecholamines or the sympathetic state of the patient. I am sure that the situations in which the drug is tested, whether it is a resting, relaxed volunteer or a critically ill patient in an acute care setting, are very different situations and will demand different responses to the drug. I think the situation is nowhere near as clear as when the patient in the operating room is given various levels of anesthesia and we are looking at some physiologic response. This response may well be a response to the severity of anesthesia or to the depth of anesthesia. But I have two questions. The first question relates to the drug interaction with warfarin: did you see a perturbation of the prothrombin time when you gave esmolol?

Dr. Lowenthal: No.

Dr. Gray: So you would not expect an enhancement of the coumadin effect if esmolol were instituted in a previously stabilized, anticoagulated patient?

Dr. Lowenthal: That is correct.

Dr. Gray: The other question relates to the issue of the metabolic activity of ASL-8123. If I am correct, I believe you hinted at some possible physiologic effects of this moiety—I am not sure if that is correct. In any case, it did look like there was quite a prolonged period of elimination. The reason I am asking about this is that when we gave esmolol to patients with tachycardia, for instance, over a period of many, many hours, the heart rate returned to baseline very slowly when we stopped the drug. This implies that there may be either some change in the physiologic basal state of the patient or there may be some prolonged effect that is not seen with the brief infusion and cessation.

Dr. Lowenthal: I appreciate your comments, Dr. Gray, especially in regard to basal sympathetic tone in "normal" people versus patients with cardiovascular disease in the intensive care setting. However, although we did not measure catecholamines, I can tell you that when volunteers are put in bed and have various intravenous lines in their arms, and do not know the effects of this "investigational or experimental drug" and are clearly in a subservient position, that, too, can induce some increase in adrenergic tone. Clearly it is relative. However, we still did not see any changes in heart rate or blood pressure.

Dr. Gorczynski (McGaw Park, Illinois): I would like to respond to the pharmacodynamic activity of the metabolite. We tested this in two situations and if one gives extremely high metabolite concentrations, one can demonstrate a reduction in isoproterenol-driven tachycardia. The metabolite requires 350-fold higher concentrations than you need with esmolol to blunt tachycardia, both in intact animals as well as in vitro. These are very high millimolar concentrations.

Electrophysiology of Esmolol

ALLAN M. GREENSPAN, MD, SCOTT R. SPIELMAN, MD, LEONARD N. HOROWITZ, MD, SHEILA SENIOR, RN, JAMES STECK, Senior CRM, and ATUL LADDU, MD

The electrophysiologic characteristics of esmolol were studied in 14 patients. Ten men and 4 women, mean age 57 years, were electrophysiologically evaluated at baseline, and also at 4 to 8 minutes after the administration of a maintenance infusion of esmolol. Plasma samples for esmolol blood levels were drawn at 10 minutes of the maintenance infusion, at the end of the maintenance infusion and 30 minutes after the maintenance infusion was discontinued. Results of this study showed that esmolol has typical β-blocker electrophysiologic effects. Its major action was on sinus node function; it prolonged this basic sinus cycle length but had no significant effect on intrinsic automaticity as reflected by the corrected sinus node recovery time and sinoatrial conduction. Direct effects on atrioventricular (AV) nodal function were reflected by effects on AV nodal conduction and refractoriness. There was no direct effect on atrial function and, as expected, no effect on His-Purkinje or ventricular function. The intensity of esmolol's electrophysiologic effects on sinus node function, AV nodal conduction and AH interval is comparable to those of other β blockers.

(Am J Cardiol 1985;56:19F–26F)

Acute interventions to control atrial tachyarrhythmias frequently require the parenteral administration of β blockers to patients with impaired left ventricular function, who are further compromised by the toxic or metabolic derangements of their acute clinical situation.[1–3] Under these circumstances, patients are particularly susceptible to the negative inotropic and bronchospastic adverse effects of β blockers, which can actually worsen the clinical situation.[4] Thus the development of a very short-acting β blocker—whose electrophysiologic and hemodynamic effects could be rapidly initiated and reversed to adapt to the changing requirements of such acute clinical situations—would be of major benefit. Esmolol, a newly developed parenteral β blocker, has an ultrashort elimination half-time (9 minutes) and might satisfy the criterion for a rapidly acting agent to be used in such acute metabolic derangements. We therefore characterized the electrophysiologic effects of esmolol in 14 hospitalized patients undergoing clinical electrophysiologic studies for various indications.

Methods

The characteristics of the study population are outlined in Table I. Ten men and 4 women, mean age 57 years, gave informed consent for the administration of intravenous esmolol after routine clinical electrophysiologic study. Ten of the 14 patients had organic heart disease; most had coronary disease with a previous myocardial infarction. As a group, left ventricular systolic function was mildly decreased, but 3 patients had severe dysfunction (with ejection fractions of 11, 27 and 33%). The most common indication for electrophysiologic study was syncope and the most common finding at clinical electrophysiologic study was an inducible ventricular tachyarrhythmia. The study protocol is illustrated schematically in Figure 1. Patients underwent routine clinical electrophysiologic studies with 3 multipolar electrode catheters positioned under local anesthesia in the high right atrium, atrioventricular (AV) junction and right ventricular apex. Standard measurements of sinus node, AV node, atrial, His-Purkinje and ventricular function were made as outlined in Table II.

After the baseline electrophysiologic study, esmolol was administered in a 2-stage infusion. There was an initial loading phase of 500 μg/kg/min for 3 to 5 minutes, followed by a maintenance infusion of 300 μg/kg/min that was continued until completion of the electrophysiologic measurements, i.e., 8 to 40 minutes. After the maintenance infusion ended, esmolol was allowed to wash out for 30 minutes to achieve baseline conditions. Patients 1 to 5 received a 3-minute loading infusion, while patients 6 to 14 received a 5-minute loading infusion. Electrophysiologic measurements were initiated at 4 to 8 minutes of the maintenance infusion and 30 minutes after termination of the infusion. On average, the measurements were completed in 18 minutes.

Plasma samples for esmolol levels were obtained at 10 minutes of the maintenance infusion, at the end of the maintenance infusion and at 30 minutes after washout. The cuff blood pressures and the sinus cycle length were measured every 5 minutes throughout the course of the experimental protocol.

TABLE I Patient Characteristics (n = 14)

Age	57 (28–73)
OHD	10 (6—CAD, 3—VHD, 1—CM)
Ejection fraction	48% (11 to 72%)
Indication for EPS	9—syncope, 3—VTA, 1—SSS
EPS findings	6—inducible VTA, 2—CSH, 1—↑HV

CAD = coronary artery disease; CM = cardiomyopathy; CSH = carotid sinus hypersensitivity; EPS = electrophysiologic study; OHD = organic heart disease; SSS = sick sinus syndrome; VHD = valvular heart disease; VTA ventricular tachyarrhythmia.

Statistical evaluations were performed by analysis of variance and all measured values are reported as mean ± standard deviation. Because there were no significant differences by analysis of variance in either the mean plasma esmolol levels or the mean values of electrophysiologic parameters between the 2 groups with differing loading infusions, the data from these groups were pooled and analyzed together.

Results

Electrophysiologic effects during infusion: The major electrophysiologic effects of esmolol were on sinus node and AV nodal function. As shown in Figure 2, esmolol significantly prolonged the basic sinus cycle length and the sinus node recovery time. However, esmolol did not influence the sinoatrial conduction time or the corrected sinus node recovery time. Figure 3 illustrates the direct effects of esmolol on AV nodal

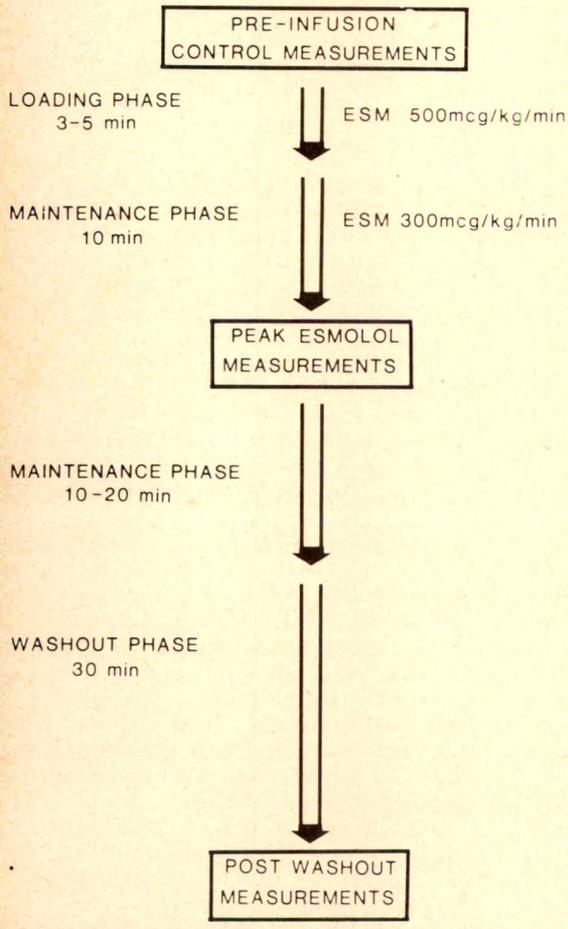

FIGURE 1. Schematic illustration of the experimental protocol. Electrophysiologic measurements were made before the 2-stage esmolol (ESM) infusion, beginning at 4 to 8 minutes of the maintenance phase and 30 minutes after termination of the maintenance phase. Loading dose = 500 μg/kg/min for 3 minutes (5 patients) and 500 μg/kg/min for 5 minutes (9 patients).

DBP = diastolic blood pressure; NSR = normal sinus rhythm; SBP = systolic blood pressure.

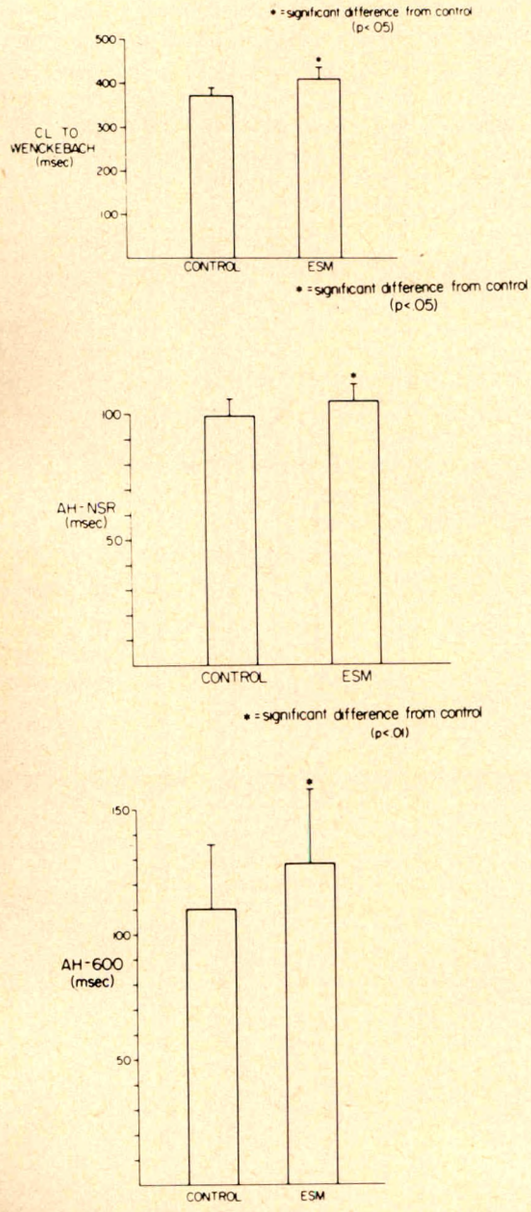

FIGURE 3. Effects of esmolol (ESM) on parameters of AV nodal function during the maintenance infusion. Esmolol significantly prolonged the cycle length to Wenckebach, **top,** the AH interval measured during sinus rhythm, **middle,** and the AH interval at an atrially paced cycle length of 600 milliseconds, **bottom.**

function. Esmolol significantly increased the cycle length at which Wenckebach periodicity developed and the AH interval measured during sinus rhythm and at a paced atrial cycle length of 600 ms. Esmolol, however, did not alter AV nodal refractoriness or retrograde AV nodal conduction time. Esmolol also showed no direct effects on atrial, His-Purkinje or ventricular function.

Electrophysiologic effects after termination of the infusion: All electrophysiologic parameters were remeasured 30 minutes after termination of the infusion when plasma drug levels were projected to be negligible. At this time, most parameters had reverted to predrug control levels, although some parameters fell significantly below control levels, reflecting an overshoot.

Effects on electrocardiographic intervals and blood pressure: Figure 4 illustrates the effects of esmolol during and after the infusion on systolic blood pressure; Table III lists the responses of electrocardiographic intervals to esmolol. There were no significant changes in blood pressure or any of the electrocardiographic intervals during either phase of the protocol.

Time course of the beta-blocking effect: Using the change in sinus cycle length as an index of electro-

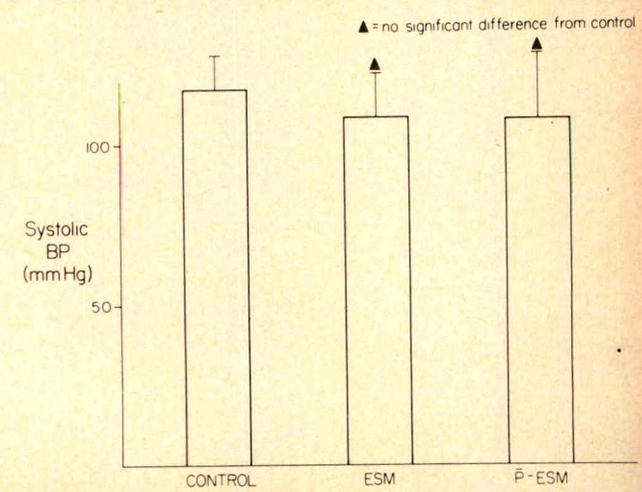

FIGURE 4. Effect of esmolol (ESM) on systolic blood pressure (BP) during, **middle,** and after, **right,** the maintenance infusion. Esmolol did not significantly lower systolic BP during either circumstance.

TABLE IV Esmolol Plasma Levels

Infusion Time	Plasma Level (μg/ml)
Control	<0.05
MP 10 min	0.90 ± 0.54
MP end	1.05 ± 0.42
MP 10 min (300 μg/kg/min × 3 min load)	0.84 ± 0.68
MP 10 min (500 μg/kg/min × 5 min load)	0.97 ± 0.39

MP = maintenance phase.

physiologic β-blocking action, the time course of esmolol's β-blocking effect is shown in Figure 5. Esmolol significantly prolonged the sinus cycle length within 5 minutes of initiating the infusion. The effect was reversed within 5 minutes of terminating the infusion.

Plasma esmolol levels: Table IV lists the plasma esmolol levels present before the infusion and at 10 minutes of the infusion for the total study population and for the 2 subgroups with differing loading doses. There were no detectable esmolol levels before the infusion, and the infusion did produce significant plasma concentrations. There was no significant difference in the plasma levels achieved by the 2 loading doses.

Discussion

General electrophysiologic profile: Esmolol is a newly developed β blocker with rapid pharmacodynamics that might be useful in acute antiarrhythmic interventions to control arrhythmias influenced by alterations in adrenergic tone. A number of studies have examined the electrophysiologic actions of various β blockers administered intravenously and with only minor variation, they have a common electrophysiologic profile. These intravenous β blockers mainly alter sinoatrial nodal and AV nodal function, variably influence atrial function and the corrected QT interval and have no effect on His-Purkinje and ventricular function.[5–11]

The present study demonstrates that esmolol has typical β-blocking electrophysiologic effects. Its major action was on sinus node function; it prolonged the basic sinus cycle length, but had no significant effect on intrinsic automaticity as reflected by corrected sinus node recovery time or sinoatrial conduction. Direct effects on AV nodal function were reflected by effects on AV nodal conduction and refractoriness. There was no direct effect on atrial function and, as expected, no effect on His-Purkinje or ventricular function.

Comparative time course of electrophysiologic effects: Although the onset of esmolol's electrophysiologic effect is no more rapid than other intravenous β blockers, its regression of this action is much faster. Using sinus cycle length as an index, significant electrophysiologic changes were detectable within 5 minutes of initiating the esmolol infusion, as it was for intravenous metoprolol[7] and acebutolol.[8] However, the reversal of esmolol's electrophysiologic effect occurred within 5 minutes of terminating the infusion; in contrast, these effects persisted with the other β blockers for 30 to 45 minutes (Fig. 6).

The rapidity of the reversal of esmolol's electrophysiologic effects compared with other β blockers is paralleled by its comparatively rapid pharmacodynamics. Esmolol's elimination half-time (9 minutes) is

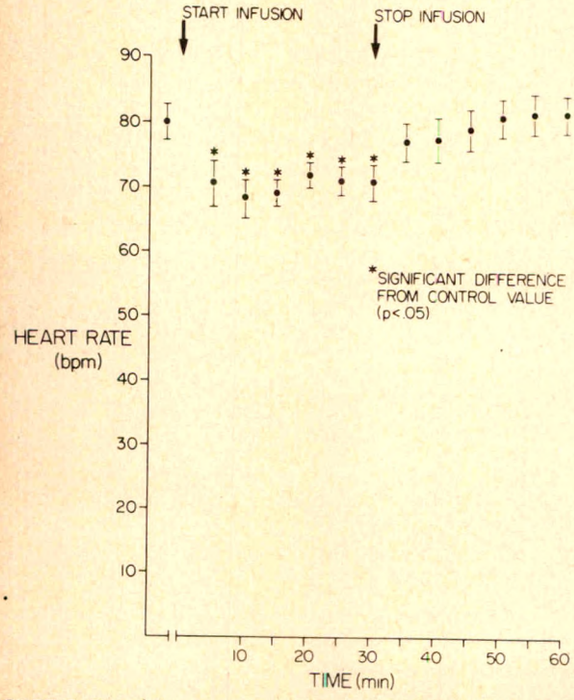

FIGURE 5. Plot of the mean heart rate (ordinate) for the 14 patients versus time (abscissa), before, during and after esmolol infusion. The mean heart rate was significantly reduced compared with control within 5 minutes of initiating the infusion; it increased to control levels within 5 minutes of terminating the infusion. bpm = beats/min.

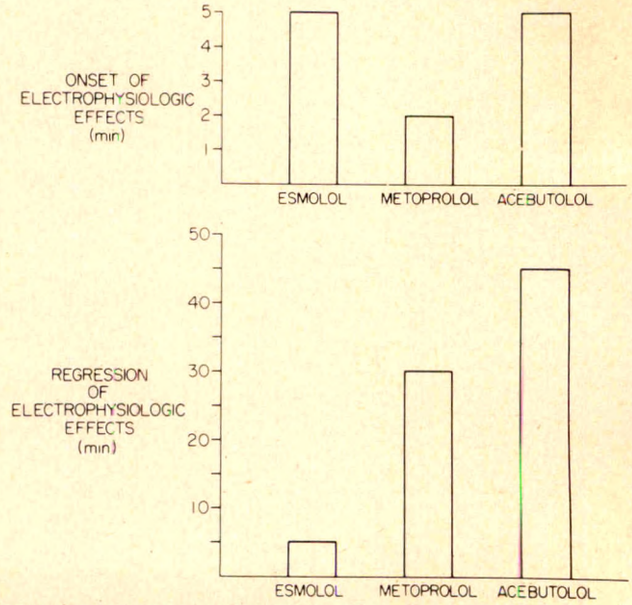

FIGURE 6. Time course of esmolol's electrophysiologic effects that prolong sinus cycle length is compared with those of metoprolol and acebutolol. The onset of esmolol's electrophysiologic effect does not differ from that of the other 2 β blockers; however, its time of regression is quite different.

much shorter than the others, which range from 2 to 3 hours for acebutolol to 6 to 9 hours for atenolol.

Comparative intensity of esmolol's electrophysiologic effects: The intensity of esmolol's electrophysiologic effects on sinus node function is comparable to those of other β blockers. As shown in Figure 7, esmolol prolonged the sinus cycle length to the same degree as metoprolol[7] and acebutolol.[8] Similarly, esmolol's effect on AV nodal conduction characteristics was of similar intensity to those of other β blockers. Esmolol increased the AH interval to an extent similar to metoprolol,[7] timolol[10] and propranolol.[11] In contrast, the electrophysiologic action of esmolol on AV nodal refractoriness was less intense than that of the other β blockers.

Clinical Applications

The efficacy of β-blocking drugs in the control of supraventricular tachyarrhythmias and ventricular ectopy is established.[12,13] In this regard, β blockers are particularly useful in the therapy of supraventricular tachyarrhythmias arising from cardiac structures rich in sympathetic innervation, i.e., sinoatrial and AV nodes, arrhythmias dependent on elevated sympathetic tone or catecholamine levels that occur in acute, toxic metabolic derangements and ventricular arrhythmias associated with inhomogeneous repolarization secondary to inhomogeneous sympathetic neural influences. The specific clinical utility of esmolol would be in the treatment of arrhythmias usually responsive to β blockers but occurring in patients with a high risk for untoward effects of β blockade. In patients with underlying left ventricular dysfunction, obstructive pulmonary disease or myocardial depressant effects of the toxic condition, esmolol provides a measure of safety unavailable with other β blockers, because of the capability for rapid reversal of its β-blocking action if congestive heart failure or bronchospasm supervene. Thus, esmolol would be very useful for the treatment of supraventricular tachyarrhythmias, i.e., PSVT or atrial fibrillation, that occur postoperatively, particularly after cardiac surgery. In paroxysmal atrial fibrillation or automatic atrial tachycardia that occurs in the setting of acute respiratory failure secondary to chronic obstructive pulmonary disease, esmolol could provide rate control or suppression of the arrhythmia while its plasma concentration could be titrated to minimize bronchospasm. Similarly, esmolol could be very useful in controlling paroxysmal atrial fibrillation or automatic atrial tachycardia associated with sepsis or an acute myocardial infarction in patients in whom myocardial depressant effects of β blockade are a concern. Finally, esmolol could be helpful in the therapy of Torsades des pointe secondary to drug or metabolically induced long QT syndrome.

Esmolol could also be particularly useful when short-term β-blocker intervention is indicated. Specifically, esmolol would be useful for acute drug testing in the clinical electrophysiologic laboratory when testing the efficacy of β blockers to control reentrant SVT. Esmolol would also be appropriate in the therapy of intraoperative supraventricular tachyarrhythmias associated with induction of anesthesia.

In summary, esmolol is a β-adrenergic blocking agent with typical electrophysiologic actions on sinus node and AV nodal function. Its intensity is comparable to that of other intravenous β blockers. Unlike the other β blockers, however, esmolol has a very rapid onset and reversal of its electrophysiologic effects, which makes it particularly suited for acute antiarrhythmic interventions to control arrhythmias in clinical situations where the risk of untoward effects of β blockade is high.

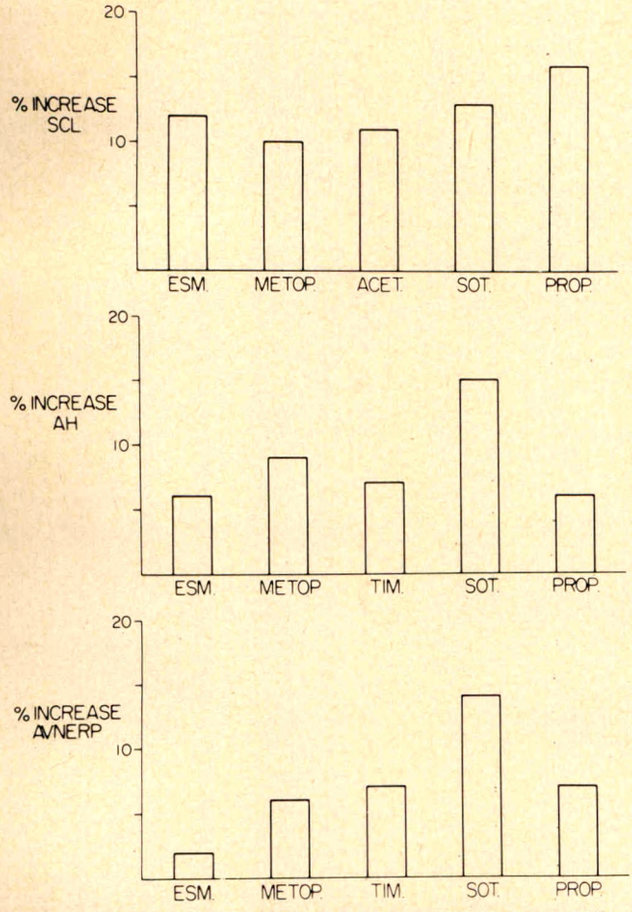

FIGURE 7. Effects of esmolol (ESM) are compared with those of other β blockers on sinus cycle length (SCL) **top,** AH interval **middle,** and AV nodal effective refractory period (AVNERP) **bottom,** as percentage increased with respect to control. Esmolol's effect on SCL and AH interval is generally comparable to those of the other β blockers, but its effect on AV nodal refractoriness is less pronounced. ACET = acebutolol; METOP = metoprolol; PROP = propranolol; SOT = sotalol; TIM = timolol.

Discussion

Dr. Reves (Durham, North Carolina): Were any of the patients on digoxin or propranolol and, if so, have you any information about the interactions in terms of electrophysiologic effects of those 2 drugs?

Dr. Greenspan (Philadelphia, Pennsylvania): No, the patients were specifically not on digoxin or propranolol at the time, because we were going to be giving a β blocker and we were particularly careful about that. Only a few patients had some degree of left ventricular dysfunction, but they were not on either digoxin or propranolol.

Dr. Lowenthal (Philadelphia, Pennsylvania): Would you know whether there was any effect of esmolol on sinoatrial and atrioventricular function that mimes that of verapamil?

Dr. Greenspan: I have not specifically seen any data on this, but we know that verapamil has significant effects on atrioventricular nodal conduction time and atrioventricular nodal refractoriness, and it can have effects on sinus node function because of its calcium-blocking effect. In terms of comparable intensity, I think verapamil is probably significantly more effective in suppressing atrioventricular nodal conduction than are most of the β blockers. If one is going to address the question of the drug of choice in treating a patient who has paroxsymal supraventricular tachycardia and walks into the emergency room, I think there would be no doubt that, assuming there was no significant degree of left ventricular dysfunction, you would reach for verapamil first. However, in a patient in the hospital, where high catecholamine tone is going to be an important inciting factor in these arrhythmias, one should give consideration to esmolol. I have seen β blockers work better for postoperative atrial fibrillation, particularly after cardiac surgery, than digoxin or other interventions that might have more intense atrioventricular nodal blocking effect, because of the specific effects of β blockers on sympathetic tone.

Dr. Iskandrian (Philadelphia, Pennsylvania): What was the duration of the infusion? In atrial fibrillation, does esmolol slow the rate, or does it convert it to sinus rhythm?

Dr. Greenspan: The second question probably should be directed to Dr. Morganroth, who is going to be presenting data specifically on that. Esmolol does convert atrial fibrillation in some cases, although the major effect was that esmolol slows the heart rate rather significantly and in a fashion comparable to propranolol. As far as the duration of our infusion, it varied depending upon the duration of time it took to make the electrophysiologic measurements, but on average we started making the measurements at 10 minutes of the maintenance infusion, and it took about 18 to 20 minutes. So the total duration of the maintenance infusion was about 30 minutes. There is some degree of variability in making these electrophysiologic measurements if the patient does not cooperate in terms of showing us a good His potential. We have to reposition catheters and so on and that can create some problems with the duration of the measurements.

Dr. Laddu (McGaw Park, Illinois): In the figure showing the heart rate effect over baseline, clearly there was a significant decrease in the heart rate in the esmolol infusion. Then when esmolol was discontinued, the heart rate slipped back so much that there was an overshoot beyond baseline. I find that very interesting because in some of our studies where we gave the drug for half an hour, 4 hours or even 24 hours continuously in patients with supraventricular tachycardia, we did not see that feature. There was no overshoot, and heart rates at the end of the infusion were at the level of the baseline or slightly lower. How would you account for that difference?

Dr. Greenspan: I would invoke Dr. Gray's caveat that we have to consider what the clinical situation is when we are talking about the response of this drug. Patients with supraventricular tachycardia have their catecholamine levels significantly raised because they have to combat the rather rapid rate and shortened filling time to maintain normal cardiac output. When you stop the drug, there may be differences in the response time than if you have a patient in whom you have just been doing some pacing and has not necessarily been in supraventricular tachycardia for a long time. Again, our study patients were in the electrophysiologic laboratory, being instrumented in a relatively unphysiologic situation compared with normal volunteers who just have intravenous lines in place. That might make a difference in the general level of their sympathetic tone. Also, of course, their underlying left ventricular function would make a difference. So, I am not sure that we should expect to see exactly the same kind of responses in our patient group as in either of the other 2 treatment groups that you have talked about.

Dr. Laddu: One possibility is that your patients who are going for electrophysiologic testing are on sedatives, and perhaps by the time you are going for the post-esmolol effect, the sedative is wearing off.

Dr. Greenspan: I think that is a very good point and it bears looking into. There are two things we can do. We can go back and look at our patients to determine what additional medications were given, and when. We can look to see where the diazepam was given and whether or not it was discontinued later in the study. We can also get an idea of how the patients were responding as there were comments made in those charts about how comfortable a patient was. The other thing we can do is to look at that prospectively in a new group of patients, i.e., just look at cycle length and heart rate at the beginning and the end of the electrophysiologic study, and see if there is a significant effect there. Clearly, the patients are more uncomfortable at the end of the procedure after lying flat for 2 to 3 hours.

Dr. Sonnenblick (Bronx, New York): But the effects were relatively small and you did not have a masked tachycardia occurring on anybody. I think it is important not to worry just about the averages, but also the extent and whether there were exceptions. Did you find anybody with the type of overshoot that might be detrimental?

Dr. Greenspan: No, actually not. It was pretty uniform. The standard deviations are not large and virtually all of the

patients showed small reversal of the effect. I would not be concerned about that clinically.

Dr. Sonnenblick: The other thing you might consider is that it is probably unfair to say that the onset of action is 5 minutes when the first measurement was made at 5 minutes.

Dr. Greenspan: Absolutely. That point is very well taken. I think if I were to do the study over again I would start sampling much earlier on because the onset appears to be sooner than 5 minutes.

Dr. Lee (McGaw Park, Illinois): Your comparative figure with esmolol and the other β blockers showed that the effects of esmolol were comparable, with the exception of the atrioventricular nodal effective refractoriness. Given the fact that in atrial flutter and fibrillation, you get comparable lowering of ventricular rate, do you see any clinical significance in the fact that esmolol doesn't lower atrioventricular nodal effective refractory period?

Dr. Greenspan: It is sometimes very, very hard to extrapolate from the changes that one sees in the electrophysiology laboratory when making static measurements of the atrioventricular nodal function in one clinical situation to situations of arrhythmias. Here, you are looking at the AH interval during sinus rhythm and then at a rate of 100 beats/min. If one then looks at the effect of that drug in someone who is in paroxysmal atrial fibrillation or supraventricular tachycardia at 160 or 180 beats/min, I think we might unmask more intense effects. One could look at that effect by pacing faster and seeing if one uncovers a stronger effect. I think that is one of the reasons why we do not see much of an effect in the static measurement of atrioventricular nodal refractoriness, and yet it can have significant effects on the clinical situation. Therefore, if one looks at measurements of other antiarrhythmic effects, such as those of the membrane-active antiarrhythmic agents on ventricular refractoriness or conduction, one would be hard pressed to see a correlation between that and some of the very intense effects in terms of suppressing ventricular tachyarrhythmias.

Effects of Esmolol on Cardiac Function: Evaluation by Noninvasive Techniques

ABDULMASSIH S. ISKANDRIAN, MD, A-HAMID HAKKI, MD, and ATUL LADDU, MD

In a double-blind, randomized, crossover study, the effects of esmolol and propranolol were examined at rest and during peak upright exercise in 15 patients. At rest, both esmolol and propranolol significantly decreased heart rate, systolic blood pressure, rate-pressure product, left ventricular ejection fraction, cardiac index and right ventricular ejection fraction. During exercise, significant decreases were also found in heart rate, systolic blood pressure and cardiac index in both treatment groups. No significant differences were found between mean esmolol and mean propranolol measurements at rest and during exercise, except for the exercise systolic blood pressure, which was lower during esmolol infusion. Blood levels of esmolol decreased markedly by 30 minutes postinfusion, as did its β-blocking action. Esmolol was well tolerated with no important local, systemic or laboratory abnormalities. Thus, the effects of esmolol on cardiovascular performance at rest and during exercise are similar to those of propranolol.

(Am J Cardiol 1985;56:27F–32F)

Beta-adrenoceptor blocking drugs differ considerably in pharmacodynamic and pharmacokinetic properties. In recent years considerable attention has been given to such properties as cardioselectivity and intrinsic sympathomimetic activity. Propranolol, a nonselective β-adrenergic blocking agent without intrinsic agonistic activity, has been shown to decrease heart rate, systolic blood pressure and cardiac output, and to increase left ventricular (LV) filling pressure and systemic vascular resistance.[1] Its effects on LV ejection fraction (EF) have been evaluated in normal subjects both at rest and during exercise. These reports indicate that propranolol decreases LVEF at rest and blunts the exercise-induced increase in EF expected in normal subjects.[2–4] In patients with coronary artery disease, propranolol at rest produced either no change or a decrease in LVEF.[5] However, in these patients during exercise, propranolol has been shown to either increase[6,7] or produce no change[8,9] in EF. Therefore, in patients who have exercise-induced myocardial ischemia, β-adrenergic blockers may, by decreasing myocardial oxygen demand, decrease or prevent the development of ischemia and, hence, improve the EF.

Currently available β blockers have a relatively long duration of action and thus must be used with caution in patients who cannot tolerate β blockade due to the presence of such contraindications as history of congestive heart failure and chronic obstructive lung disease. Ideally, a β blocker with an ultrashort half-life whose action could be terminated rapidly if needed is desirable in these patients. Esmolol, a cardioselective β blocker with no intrinsic sympathomimetic activity, has been shown to be ultrashort-acting with a 9 minute half-life.[10]

This report compares the effects of esmolol with those of propranolol, at equipotent β-blocking doses, on cardiovascular performance in patients evaluated by noninvasive techniques.

Materials and Methods

The hemodynamic effects of esmolol were compared with those of propranolol in a double-blind, randomized, crossover study. The study drug sequence was determined using a computerized randomization schedule. The investigator remained blinded throughout the study as to which study drug was administered on the 2 drug study days. Blinding was achieved by having concurrent infusions and injections on the drug days. Esmolol was administered using an infusion schedule and propranolol was administered by an injection schedule. However, on each drug study day, only 1 of the treatments contained an assigned study drug while the other contained a matching placebo. The study consisted of 3 study days, each separated by at least 48 hours from the preceding study day. The first day was for the baseline study. On the remaining 2 study days, the patients received an esmolol infusion on 1 day and propranolol on the other according to the order specified in the randomization schedule. On the baseline study day, each patient underwent a 30- to 45-minute stabilization period followed by radionuclide angiography at rest and during peak upright exercise.

Results are expressed as mean ± standard error of the mean. # probability value (p) < 0.05 was considered significant.
CI = cardiac index; DBP = diastolic blood pressure; Ex = exercise; HR = heart rate; LVEDV = left ventricular end-diastolic volume; LVEF = left ventricular ejection fraction; LVESV = left ventricular end-systolic volume; NS = no significant difference between treatments (p >0.5); PBV = pulmonary blood volume; PTT = pulmonary transit time; RPP = rate-pressure product; RVEF = right ventricular ejection fraction; SBP = systolic blood pressure; WI = workload; WMS = wall motion score.

On drug treatment days, study drugs were administered after a 30- to 35-minute stabilization period. The esmolol infusion schedule required a 2-minute loading infusion at a rate of 500 μg/kg/min, followed by a constant infusion rate of 200 μg/kg/min (esmolol was diluted in normal saline to achieve a final concentration of 10 mg/ml), which was continued until both the rest and exercise radionuclide angiograms were completed. Propranolol was administered as four 1-mg injections, each of which was administered over 1 minute. At approximately 12 minutes after initiation of study drug, each patient underwent radionuclide angiography at rest and during peak exercise. The heart rate and blood pressure were recorded every 2 minutes during infusion and every 5 minutes for 30 minutes after the end of infusion on both study days. Blood samples for esmolol levels were collected at rest approximately 12 minutes after the start of infusion, during peak exercise and at 30 minutes postinfusion. Safety data consisting of blood chemistry, hematology and urinalysis were evaluated on the baseline day and 30 minutes postinfusion on both drug study days.

There were 15 patients in this study, 12 men and 3 women between the ages of 45 and 66 years. These patients were being evaluated by exercise testing for anginal symptoms.

The radionuclide angiograms were performed with the first-pass method using a computerized multicrystal camera (Baird-Atomic, System-77). The resting studies were performed while the patient was seated in the upright position on the bicycle ergometer and the exercise studies were performed during peak upright exercise. On the baseline day a symptom-limited, upright exercise was performed and exercise was terminated when the patient had excessive fatigue, leg weakness or chest pain. From the exercise data on the baseline day, workload and exercise duration were determined for each patient, and during the subsequent 2 drug study days, the exercise was terminated at precisely the same exercise workload and duration that was achieved during the baseline day. During exercise and recovery, 3 electrocardiographic leads (II, V_5 and aVF) were constantly monitored. The radionuclide angiograms were processed with the software incorporated into the multicrystal camera. The following data were obtained from the radionuclide angiograms: LVEF, LV end-diastolic volume, end-systolic volume, stroke volume, cardiac output, mean pulmonary transit time, pulmonary blood volume and right ventricular (RV) EF. LV wall motion was assessed in 3 segments—anterior, apical and inferior—and each segment was assessed on a

GURE 1. Both esmolol and propranolol significantly lowered the heart rate, systolic blood pressure and double product at rest and during exercise.

scale of 0 to 4: 4 = normal motion, 3 = mild hypokinesia, 2 = moderate hypokinesia, 1 = severe hypokinesia and 0 = akinesia or dyskinesia. The methods of measuring the various radionuclide descriptors and their reproducibility and correlation with other measurements obtained during cardiac catheterization have been described in detail from this and other laboratories.[11,12]

Results

Eight patients received esmolol on the first drug study day and propranolol on the crossover day; 7 patients received propranolol on the first drug study day and esmolol on the crossover day. There were no adverse local or systemic reactions and no clinically important laboratory changes.

The hemodynamic data at rest and during exercise in the baseline study day and the 2 drug study days are shown in Table I and in Figures 1, 2 and 3. At rest, significant drug effects were found in a number of these measurements; the most important were the heart rate, systolic blood pressure, rate-pressure product, LVEF, RVEF, cardiac index and systolic blood pressure to end-systolic volume ratio. The control measurements were significantly higher than esmolol and propranolol measurements, but no significant differences were found between the average esmolol and the average propranolol effects.

Similarly, during peak exercise, significant treatment effects were found for the heart rate, systolic blood pressure, rate-pressure product, cardiac index, RVEF and mean pulmonary transit time. It should be noted that the RVEF was measured in only 12 patients. In the remaining 3 patients, the RV images were not totally contained in the gamma camera's field of view and therefore the RVEF could not be measured reliably. The average baseline measurements were significantly higher than both the average esmolol and the average propranolol measurements except in pulmonary transit time. Also, with the exception of the exercise systolic blood pressure (esmolol, 155 mm Hg; propranolol, 163 mm Hg), no significant differences were found between esmolol and propranolol in the measurements just described (Table I). There was no significant treatment effect on exercise LVEF, end-diastolic or end-systolic volumes. The hemodynamic changes at rest and exercise were similar among patients with resting baseline LVEF ≥50% (n = 10) and among patients with resting baseline EF of <50% (n = 5).

TABLE II Blood Levels of Esmolol and Its Inactive Metabolite ASL-8123* (mean ± standard error of the mean)

Study	Pts (n)	Infusion	30 Minutes Postinfusion
Esmolol	7	0.59 ± 0.07	0.01 ± 0.01
ASL-8123 (μg/ml)	7	2.20 ± 0.20	8.55 ± 0.50

*Blood levels were not available on all patients. The relative potency of metabolite is 1/320th of the parent compound.

This study was not designed to compare the effect of esmolol and propranolol on exercise-induced ischemic changes. However, the data show that the incidence of ST-segment changes and arrhythmias was greatly reduced in both treatment groups compared with the baseline period. These changes did not reach significance, probably owing to the small sample size.

Because of its rapid metabolism, esmolol blood levels decreased from 0.59 ± 0.07 μg/ml during infusion to 0.01 ± 0.01 μg/ml at 30 minutes postinfusion. The blood level of the inactive metabolite ASL-8123 (1/320th the potency of esmolol) continued to increase up through the final sampling time. These results are comparable to those obtained in the open-label study with invasive hemodynamic monitoring (Table II).

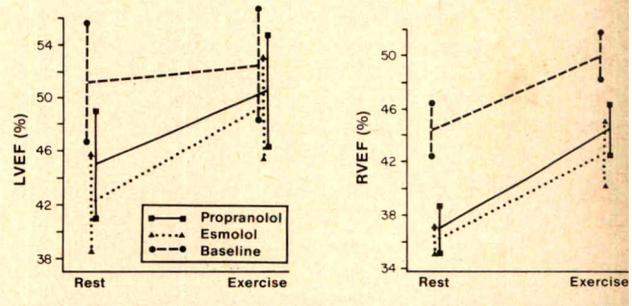

FIGURE 2. Effects of esmolol and propranolol on rest and exercise left ventricular ejection fraction (LVEF) and right ventricular ejection fraction (RVEF).

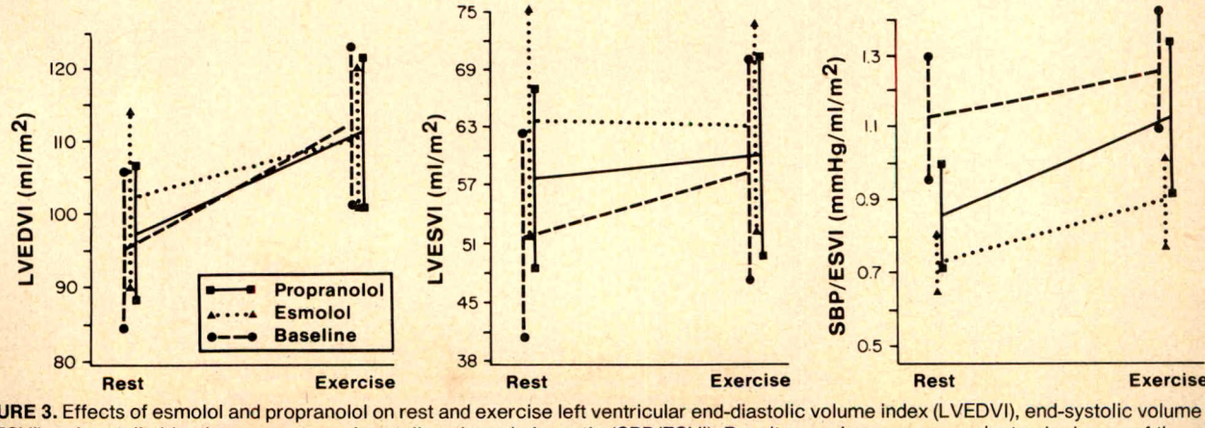

FIGURE 3. Effects of esmolol and propranolol on rest and exercise left ventricular end-diastolic volume index (LVEDVI), end-systolic volume index (LVESVI) and systolic blood pressure-to-end-systolic volume index ratio (SBP/ESVI). Results are shown as mean ± standard error of the mean.

Discussion

Esmolol, when given intravenously, produces hemodynamic changes typical of β-adrenergic blockade.[1] These changes are rapidly reversed upon discontinuation of infusion consistent with the short half-life of esmolol.[10,13] In this double-blind, randomized, crossover study, the hemodynamic effects of esmolol were very similar in magnitude and direction to those of intravenous propranolol.[13] At rest, esmolol, like propranolol, produced a decrease in heart rate, systemic pressure, cardiac index and stroke work index. There was a modest but statistically significant depression in LV function characterized by a decrease in EF and an increase in LV filling pressure and end-systolic volume. Esmolol and propranolol also decreased the resting RVEF. During exercise, esmolol produced a decrease in heart rate, systemic pressure, cardiac index and RVEF. Once again, the changes during exercise were similar to those produced by propranolol. Neither esmolol nor propranolol had significant effects on exercise LVEF, end-diastolic volume and end-systolic volume.[13] Esmolol up to a dose of 300 μg/kg/min was well tolerated with no adverse local or systemic effects.

The hemodynamic effects of β-blocking agents (decreased heart rate, blood pressure, cardiac index and stroke work index) typically result in decreased oxygen consumption by the myocardium, and thereby have a beneficial effect in the therapy of ischemic heart disease.[14–16] The accompanying modest depression of LV function characterized by a decrease in LVEF could become a problem in treating the sensitive patient with acute ischemic heart disease (acute myocardial infarction or unstable angina pectoris). Esmolol, because of its short half-life, may offer a safer alternative to such long-acting β blockers as propranolol in these acute settings. Should dangerous adverse effects occur, they could be readily reversed by termination of the infusion. Further studies are in progress to evaluate the hemodynamics and safety of esmolol in patients with depressed LV performance. Pending the outcome of those studies, esmolol may be the β-blocking agent of choice in the treatment of patients with acute myocardial infarction.

Discussion

Dr. Gray (Los Angeles, California): To better understand the type of patients in your radionuclide study, I assume they were being evaluated prospectively for ischemic heart disease. I would gather from their ejection fraction response that this was not the ultimate diagnosis in all patients. Their resting ejection fractions were in the borderline-to-normal range, but the response to exercise was, by and large, about the same as control measurements. It did not look like there was a significant drop in ejection fraction with exercise in the control state. I would like to understand better the substrate upon which the 2 β blockers were used.

Dr. Iskandrian (Philadelphia, Pennsylvania): By and large, they were patients who had typical or atypical angina pectoris. Ten of the 15 patients had resting ejection fractions within the normal range for our laboratory—that is, about 50%. The other 5 had abnormal resting ejection fractions; all but 1 were in the low 40% range. Our second patient had an ejection fraction of 18% at rest, and he tolerated esmolol well. The response, by and large, is typical of patients with coronary artery disease; the ejection fraction did not increase with exercise, their end-systolic volume increased and they had either rest or exercise wall motion abnormalities. Diagnosis of 6 patients was confirmed either by infarction or by coronary angiogram, but the remaining 9 patients were clinically determined to have coronary heart disease.

Dr. Sonnenblick (Bronx, New York): I think it would be advantageous to show all the data. Without the discrete data points, it is like the 3 fellows who go hunting and one shoots high and the other shoots low and the third fellow says, "You got him." One would like to know if the averages reflect or mask variations in the data.

Dr. Morganroth (Philadelphia, Pennsylvania): In that regard, was there a difference between the response you observed in the single patient with 18% versus the patients with lower than normal ejection fractions?

Dr. Iskandrian: Actually we did analyze them. Let me answer Dr. Sonnenblick's question first. The whole of the individual data points are in the May 1985 issue of *The American Journal of Cardiology* and you can see them. All the data are there: patient by patient and what happened to them during both studies at rest and during exercise. We analyzed the studies in the 10 patients who had normal ejection fractions at rest and the 5 who were abnormal, and there was no significant change between the response in the 2 groups. But, mind you, of the patients with the abnormal ejection fraction, 4 of the 5 were mildly abnormal. In patients with a severe dysfunction, it may be a different issue. We are now in the process of looking at such patients, and it indeed looks like the responses might be different from the mild dysfunction.

Dr. Morganroth: In what regard?

Dr. Iskandrian: We are seeing more left ventricular dilation with the infusion of esmolol, which is something of concern if you start thinking of the myocardial oxygen demand in relation to wall stress and so on.

Dr. Morganroth: Those changes might also be different, of course, with the underlying etiology. For example, when you exercise the patient with ischemic heart disease, the β-blocking effect in ischemia may be different than if there is no coronary ischemia, such as in a patient with idiopathic cardiomyopathy. You do not have a large enough number, obviously, to look at the etiologic, mechanistic and absolute levels of ejection fraction.

Dr. Iskandrian: That is a very important point. Any evaluation of a β blocker during exercise is dependent on the patient population and the exercise protocol. It is completely different if you exercise a patient with coronary disease and during peak exercise that patient becomes ischemic, because you hope that the β blocker will decrease the double product and at the same workload he won't be ischemic. If the patient wasn't ischemic, then β-blocker response is going to be different. Mean differences sometimes hide a lot of variance beween individuals.

Dr. Gray: Is it your feeling that, in the patients with documented ischemic heart disease, esmolol or propranolol is protective of exercise-induced ischemia based on hemodynamic, clinical or electrocardiographic response?

Dr. Iskandrian: I think there is no question that β blockade is protective if that patient develops ischemia during the control measurement and if that patient is going to do the same exercise with the medication. However, if you exercise patients longer while they are on a β blocker, they may become just as ischemic as without medication.

Dr. Sonnenblick: I think what Dr. Iskandrian is saying is that with the limitation of cardiac output that they have, they may be limited in their exercise performance for noncardiac reasons. So, the problem is much more complex than the usual simple picture that was once presented.

Dr. Lowenthal (Philadelphia, Pennsylvania): Often, people on the conventional oral β blockers developed skeletal muscle fatigue during exercise, possibly related to some blunting of lipolysis and also to the decrease in cardiac output. Did you notice if this effect was also present during the esmolol component? Did they develop any lower extremity fatigue?

Dr. Iskandrian: Not really. Clinically, they tolerated it, and with most patients we stopped them when they were on the drug because we had reached our predetermined endpoint with no symptoms related to muscle fatigue.

Dr. Laddu (McGaw Park, Illinois): Esmolol was given only for a short period. Isn't the onset of fatigue a long-term effect of β blockade?

Dr. Iskandrian: That may be true, but at rest I think I suggested it in something I wrote about 5 years ago. I said that if you put patients with sick hearts on chronic β-blocker care, and they exercise, the ejection fraction is not going to be better. If the heart rate is also limited, then the cardiac output will be limited and this is why they feel so tired and have some noncardiac symptoms.

Dr. Greenspan (Philadelphia, Pennsylvania): Dr. Iskandrian, I am very fascinated by the observation that there were some differential responses in the right ventricle and the left ventricle, in terms of ejection fraction, to the β blockade. You say you have some thoughts about it and I would like to hear them. Do you think there may be geometric factors that play a role in terms of differences in the right ventricular and left ventricular response?

Dr. Iskandrian: I think that might be, but it might also be that the β receptors in the right ventricle are different in quality or quantity from those in the left ventricle. It might also be that you are dealing with an afterloading tendency. We saw from the hemodynamic changes, despite no change in end-diastolic volume, that wedge pressure and pulmonary artery pressure are increased. I think that even with exercise, these changes might not be due primarily to changing contractility of the right ventricle but to an afterload-dependent phenomenon secondary to decreased left ventricular contractility.

Dr. Gray: Actually, we did look at this somewhat tangentially, if you will, in a hypertensive study in the postcardiac surgical patient. We found the left ventricular stroke work index did decrease somewhat with esmolol. Although not tremendous, statistically significant decreases were seen with esmolol. The right ventricular stroke work index, by contrast, decreases minimally and nonsignificantly, and the main difference seems to be in the afterload effects. In other words, the work demand on the right heart is still greater. The effect of giving esmolol in contrast to, say, nitroprusside, is that the pulmonary artery systolic pressure does go up a bit more than, say, the afterload on the left side.

Dr. Sonnenblick: I agree with that.

Dr. Gray: So what is demanded of the left heart is different, and I presume catecholamines or some other hemodynamic response, reflex or otherwise, are going to be different from right to left.

Dr. Sonnenblick: I think the bottom line is how well esmolol is tolerated in this broad group of patients. I think it is very easy to make a great deal out of the changes in the ejection fraction, but there is sympathetic withdrawal there. Also, if the cardiac output and the stroke volume are decreasing, or just the stroke volume is, the ejection fraction will tend to decline on its own. In other words, ejection fraction will fall as cardiac output falls. Ejection fraction does not remain a direct indicator of contractility in that circumstance—directionally, it is probably correct, but it is not directly proportional and it is remarkably well tolerated. What you are also pointing out is there were no broad exceptions.

Dr. Iskandrian: Yes, that is true.

Comparative Efficacy and Tolerance of Esmolol to Propranolol for Control of Supraventricular Tachyarrhythmia

JOEL MORGANROTH, MD, LEONARD N. HOROWITZ, MD, JEFFREY ANDERSON, MD, PRASAD TURLAPATY, PhD, and the ESMOLOL RESEARCH GROUP*

This multicenter, double-blind, randomized, parallel study compared the effectiveness and tolerance of intravenous esmolol with intravenous propranolol in patients with supraventricular tachyarrhythmia (heart rate [HR] >120 beats/min). Efficacy was evaluated in 53 patients receiving esmolol and in 57 patients receiving propranolol. Patients randomized to esmolol received infusions of various doses of esmolol ranging from 50 to 300 μg/kg/min (each dose infused for 5 minutes) over a 30-minute titration period with intermittent placebo boluses of propranolol. Those randomized for propranolol received 1 mg/min for the first 3 minutes, and then another 3 mg from minutes 5 to 8 with continuous placebo esmolol infusion during the 30-minute titration period. A therapeutic response, defined by 20% or greater reduction in HR, HR <100 beats/min or conversion to normal sinus rhythm, was achieved in 72% of patients on esmolol compared with 69% of patients on propranolol (difference not significant). The therapeutic response was maintained in 67% of patients on esmolol and 58% of patients on propranolol (difference not significant) during a 4-hour maintenance period. Conversion to normal sinus rhythm occurred in 14% of esmolol patients and 16% of propranolol patients during titration and 10% of esmolol and 8% of propranolol patients during maintenance. After discontinuation of study drugs, a more rapid reversal of the reduction in HR was observed in esmolol patients compared with those patients receiving propranolol. Adverse reactions were seen in 29 (45%) patients on esmolol and 11 (18%) patients on propranolol. The principle adverse reaction was hypotension, which was predominantly asymptomatic and found in 23 patients receiving esmolol and 4 receiving propranolol. Hypotension resolved quickly after discontinuation of esmolol and did not cause any significant consequences.

This study demonstrates that esmolol is comparable in safety and efficacy to propranolol, and unlike propranolol, it has a much faster termination of β blocking because of its short half-life. Esmolol, therefore, has marked theoretical advantages in its use in the intensive care unit for the control of supraventricular tachyarrhythmia.

(Am J Cardiol 1985;56:33F–39F)

Beta-adrenergic blocking drugs have been standard therapy for the treatment of acute ischemic, hypertensive and tachyarrhythmic states.[1] In the intensive care unit, intravenous β blockers can provide for a rapid correction of unstable cardiovascular conditions; however, their use also involves such potential risks as serious adverse reactions including excessive bradycardia, heart block and worsening of left ventricular dysfunction. These adverse reactions usually dissipate slowly, which may restrict the use of currently available β blockers whose elimination half-lives range from 2 to 6 hours.[2] Ideally, a β blocker with an ultrashort half-life whose action could be terminated rapidly if needed is desirable in acute settings.

Esmolol, a cardioselective β blocker with no intrinsic sympathomimetic activity, has been shown to be ultrashort-acting with a 9.2-minute half-life.[3] This report details a double-blind, randomized, controlled trial that compared the efficacy and tolerance of esmolol with propranolol, both administered intravenously,

TABLE I Prestudy Variables in Baseline Comparative Patients Used for Efficacy Analysis

	Esmolol (n = 53)	Propranolol (n = 57)
Age (years)	65 ± 11	63 ± 10
Men	33 (62%)	35 (61%)
Heart rate (beats/min)	147 ± 16	146 ± 18
Systolic blood pressure (mm Hg)	126 ± 22	118 ± 15
Diastolic blood pressure (mm Hg)	78 ± 11	73 ± 11
Postoperative	27 (51%)	28 (49%)
Coronary artery disease	16 (30%)	18 (32%)
Type of SVT		
Atrial fibrillation	40 (75%)	48 (84%)
Atrial flutter	9 (17%)	8 (14%)
Automatic atrial tachycardia	3 (6%)	0
Sinus tachycardia	1 (2%)	1 (2%)

SVT = supraventricular tachyarrhythmia.

TABLE II Types of Therapeutic Response in Patients Used for Efficacy Analysis

Study Period Response	Efficacy Patients: Esmolol	Efficacy Patients: Propranolol
Entered titration period	50	55
Achieved therapeutic response*†	36 (72%)	38 (69%)
Type of therapeutic response†		
> 20% HR reduction	32 (64%)	38 (69%)
HR < 100 beats/min	16 (32%)	19 (34%)
Conversion to NSR	7 (14%)	9 (16%)
Entered maintenance period	30	36
Maintained therapeutic response*†	20 (67%)	21 (58%)
Type of therapeutic response‡		
> 20% HR reduction	20 (67%)	18 (50%)
HR < 100 beats/min	13 (43%)	15 (42%)
Maintained NSR	5 (17%)	8 (22%)
Converted to NSR	3 (10%)	3 (8%)

HR = heart rate; NSR = normal sinus rhythm.
* A patient may achieve more than 1 type of therapeutic response.
† Denominator for percentage response equals number of efficacy patients who had entered titration period.
‡ Denominator for percentage response equals number of efficacy patients who had a therapeutic response during titration and entered the maintenance period.

to control excessive tachycardia in patients with supraventricular tachyarrhythmias (SVTs).

Methods

This study was conducted in 12 centers in the U.S. using a common protocol. Patients' inclusion criteria were age older than 18 years and heart rate (HR) >120 beats/min owing to SVT. Supraventricular tachyarrhythmias were defined as the presence of atrial fibrillation, atrial flutter, ectopic atrial tachycardia or sinus tachycardia of cardiac origin. Patients with preexcitation syndromes were excluded. Other exclusions included uncontrolled congestive heart failure or hypotension (<100/70 mm Hg), ventricular arrhythmias requiring acute therapy, severe disorders of impulse conduction, such as sick sinus syndrome, atrioventricular block and tachycardia due to an external condition, such as anemia or infection. Patients with electrolyte imbalance, chronic obstructive pulmonary disease, asthma that precluded β blockade or prior allergy to a β blocker were also excluded. Patients who had been on monoamine oxidase inhibitors or catecholamine-depleting agents, such as reserpine, within 6 weeks or those who had taken a β- or calcium-channel blocker within 2 half-lives of entry to the study were also excluded. Women were permitted entry if they were not pregnant.

Protocol: If patients demonstrated SVT with HR >120 beats/min for a minimum of 30 minutes (baseline period), they were randomly assigned to either an infusion of esmolol with placebo injections of propranolol or propranolol injection with placebo esmolol infusion. Esmolol was titrated upward according to patient response over 30 minutes during the titration period. Six different levels of esmolol dosing were used, each over 5 minutes. During the first minute of each of the 5-minute periods, esmolol was infused with a loading dose (500 μg/kg/min) and then for the succeeding 4 minutes, esmolol was titrated from 50, 100, 150, 200, 250 and finally to 300 μg/kg/min. Intravenous boluses of active propranolol were administered depending on patient response, in 1-mg doses over 1 minute for the first 3 minutes and then from minutes 5 to 8, thus providing 6 boluses or 6 mg of active propranolol.

During the titration period, all patients simultaneously received either active esmolol infusion and placebo propranolol injection or active propranolol injections with placebo esmolol infusion to ensure the double-blind status. Infusions were controlled with the use of a volumetric pump, which

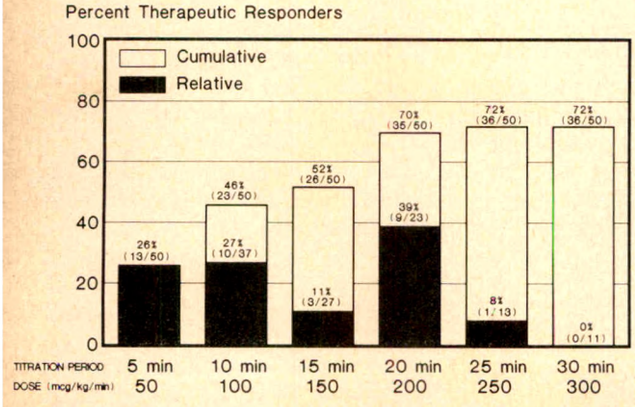

FIGURE 1. Percentage of efficacy patients achieving a therapeutic response during the titration period, by esmolol dosage. Cumulative percent is the number of responders at a given dosage or lower divided by the number of efficacy patients (n = 50). Relative percent is the number of responders at a given dosage divided by the number of efficacy patients treated with that dosage.

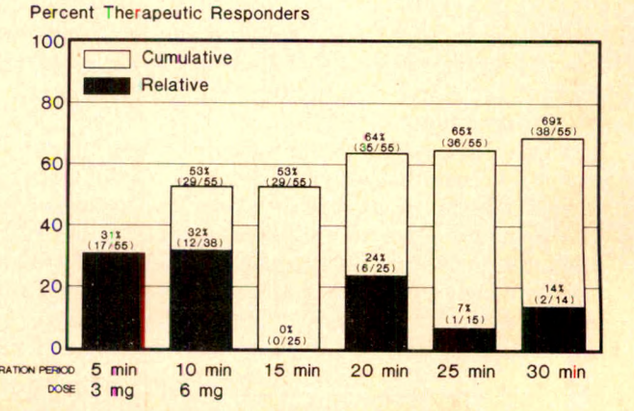

FIGURE 2. Percentage of efficacy patients achieving a therapeutic response during the titration period, by propranolol dosage. Cumulative percent is the number of responders at a given dosage or lower divided by the number of efficacy patients (n = 55). Relative percent is the number of responders at a given dosage divided by the number of efficacy patients treated with that dosage.

was standardized and calibrated at each of the 12 clinical study centers.

The therapeutic endpoints used in this study were a >20% reduction in ventricular rate compared with the average initial 30-minute baseline HR, a reduction in absolute ventricular rate to <100/min or a conversion to normal sinus rhythm.

Upon reaching a therapeutic endpoint, the patient then entered a 4-hour maintenance period using the dose infusion level at the time that the therapeutic endpoint was achieved. At the discretion of the investigator, patients not responding during titration were either entered into the 4-hour maintenance period or terminated from the study. After the maintenance period, the patients had their infusions discontinued and a 20-minute follow-up period was used to profile clinical evaluations.

Before study, data from the patient's history, physical examination, 12-lead electrocardiogram and routine laboratory analyses were recorded and these were repeated within 24 hours of the follow-up period. Blood pressure and HR were obtained every 10 minutes during the baseline period, every 5 minutes during titration, every 20 minutes during the maintenance and every 10 minutes during the follow-up period. Heart rates were determined by hand counting a 1-minute electrocardiogram rhythm strip (lead II) at each of these intervals.

Statistical analysis: A 2-way analysis of variance was used to test for differences among centers for all variables as well as differences in recruitment. Tests for center and treatment interaction effects were performed using a standard log-linear model for proportions. Two-way analysis of variance for continuous variables and a log-linear model for categorical data were used for response variables and within group comparisons were performed using the paired *t* test. Significance was defined at the 0.05 level before 2-tailed hypothesis.

Results

Enrollment and demographics: Of the 127 patients who were entered into the protocol and received 1 of the study drugs, 11 patients on esmolol and 6 on propranolol were disqualified from the efficacy analysis because of protocol deviations. Safety data will be, therefore, reported on 64 esmolol and 63 propranolol patients, whereas efficacy data will be reported on 53 esmolol and 57 propranolol patients. Efficacy data in regard to HR reduction will be reported on 50 esmolol and 55 propranolol patients because 3 patients receiving esmolol and 2 patients receiving propranolol were excluded because of investigator error in judging therapeutic endpoint.

There was no difference among the demographic and clinical characteristics of the patients randomized to esmolol and propranolol except that the diastolic blood pressure was 5 mm Hg higher among the esmolol efficacy patients (Table I). There was no significant interaction between the treatment assignment and study centers.

Efficacy: During titration, 72% (36 of 50) of patients had a therapeutic response to esmolol compared with 69% (38 of 55) of patients randomized to propranolol (NS). During the 4-hour maintenance period, 67% (20 of 30) on esmolol and 58% (21 of 36) on propranolol maintained therapeutic response. Table II details the specific types of therapeutic response during each of these 2 periods. The therapeutic response rate within each treatment group did not differ with regard to those patients younger than or over 65 years of age, gender, postoperative status or type of heart disease. There was also no difference in response rates among types of SVT between esmolol and propranolol. Therapeutic response in patients with atrial fibrillation was similar in both treatment groups: esmolol, 28 of 38 (74%) and propranolol, 34 of 46 (74%). Figure 1 details the cumulative and relative therapeutic response rates among efficacy patients randomized to esmolol during the titration period. In the esmolol group 70% (35 of 50) of patients responded to an infusion rate of ≤200 μg/kg/min. One additional patient responded at 250 μg/kg/min, while no additional patients responded to the 300 μg/kg/min dose. The average dose of esmolol in responders was 115 ± 11 μg/kg/min. Figure 2 illustrates the cumulative and relative therapeutic response rates among propranolol efficacy patients. Cumulative therapeutic response at 3 mg of propranolol was 31% (17 of 55) and at 6 mg of propranolol or less, it was 69% (38 of 55).

Response to propranolol or esmolol could not be predicted by any of the demographic characteristics except that in the propranolol treatment group, nonresponders had a higher mean HR (155 beats/min) than the responders (141 beats/min). Baseline systolic blood pressure was slightly higher among responders than nonresponders within each of the treatment groups. Concurrent digoxin therapy was also associated with a higher therapeutic response in both treatment groups. For example, 85% (22 of 26) of patients in the esmolol group who were receiving digoxin were therapeutic responders compared with 58% (14 of 24) of patients not taking digoxin who were therapeutic responders. Similarly, 75% (21 of 28) of patients in the propranolol group on digoxin were therapeutic responders compared with 63% (17 of 27) of those without concurrent digoxin were therapeutic responders.

As shown in Figure 3, during the follow-up period, the HR more rapidly reversed itself among the esmolol

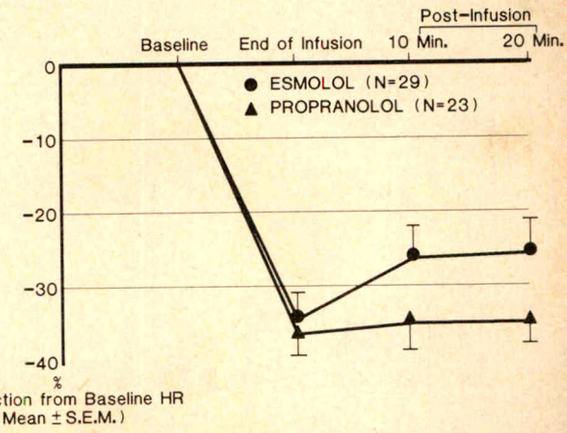

FIGURE 3. Recovery of heart rate during the follow-up period (after discontinuation of study drugs) in efficacy patients who were therapeutic responders. In esmolol-treated patients, study drug was discontinued after 4-hour maintenance period. In propranolol-treated patients, study drug was discontinued after 10 minutes in the titration period (4 hours, 10 minutes after boluses). These patients were infused with placebo esmolol throughout the 4-hour maintenance period.

TABLE III Adverse Reactions Noted During the Study

Adverse Reaction	No. of Patients*	
	Esmolol	Propranolol
Hypotension	23	4
Asymptomatic	19	3
Symptomatic	4	1
Ventricular ectopy	1	0
Excessive bradycardia	0	2
Congestive heart failure	0	1
Diaphoresis	4	0
Dyspnea, rales, cyanosis	2	2
Dizzy, weakness, headaches	2	1
Nausea, vomiting, dyspnea	0	6
Intravenous site irritations	5	0

* A patient may have more than 1 adverse reaction.

patients (within 10 minutes after discontinuation of esmolol) compared with those on active propranolol (approximately 4 hours after discontinuation of active propranolol).

Safety results: A total of 29 (45%) esmolol patients and 11 (18%) propranolol patients developed adverse reactions during the study (Table III). The most frequently reported adverse reaction was hypotension, which was symptomatic in 4 patients receiving esmolol and 1 receiving propranolol. These 4 patients received doses ≥150 μg/kg/min and hypotension resolved within 20 to 90 minutes after discontinuation of esmolol. Most patients in whom hypotension developed in the esmolol group were postoperative, had atrial fibrillation or were over 65 years of age. Premature discontinuation from the study because of adverse reactions occurred in 15 patients receiving esmolol and in 6 receiving propranolol. All esmolol patients were discontinued due to hypotension. Adverse reactions, which necessitated discontinuation among 6 propranolol patients, were: increasing heart failure (n = 1), dyspnea and cyanosis (n = 1), bradycardia and hypotension (n = 1), nausea (n = 1), nausea and hypotension (n = 1) and nausea, vomiting and headache (n = 1). One patient died in each treatment group because of development of ventricular fibrillation within 24 hours of discontinuing the β blocker and in neither case was death considered to be related to the study drug administration. The incidence of adverse reactions was higher in esmolol patients receiving ≥ 200 μg/kg/min (21 events) compared with those receiving less than this dose (13 events). Of the 17 adverse events in the propranolol group, 9 occurred in patients receiving <3 mg and 8 in those who received between the 3- to 6-mg dose. No significant differences were noted among any of the laboratory variables in patients in this study.

Discussion

Beta-blocker therapy has proved to be particularly effective in treating patients in the intensive care unit with unstable ischemic, hypertensive and arrhythmic disorders.[1] Intravenous use of metoprolol has recently been shown to be effective in decreasing the prevalence of serious ventricular arrhythmias and mortality from acute myocardial infarction.[4] The elimination half-life of β blockers, however, when used in this setting typically ranges from 2 to 6 hours.[2] Because β blockers may cause a deterioration or worsening of left ventricular dysfunction, excessive bradycardia, advanced degrees of conduction disturbances and bronchospasm, the potential use of an ultrashort-acting β blocker, particularly in the intensive care unit, would provide enhanced safety in these high-risk patients. Esmolol was recently developed and shown in animal and human studies to be a cardioselective β blocker with no intrinsic sympathomimetic activity.[5–8] The electrophysiologic data of esmolol demonstrate its rapid onset and offset of β-blocker effects on the sinus and atrioventricular node.[9]

This multicenter study demonstrated that esmolol, when infused in the dosage range of 50 to 300 μg/kg/min, was as effective as propranolol given from 3 to 6 mg over a 30-minute titration period to patients with SVT by producing a reduction in HR or conver-

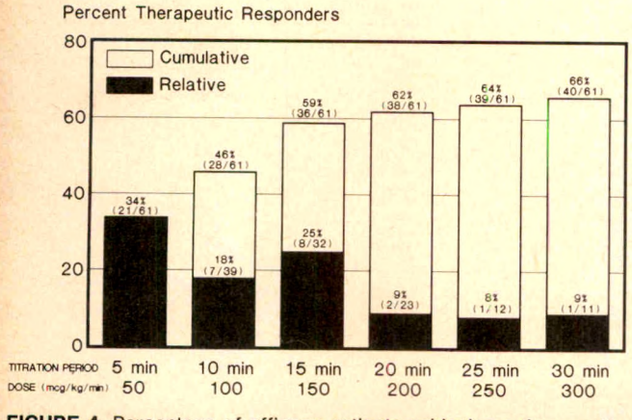

FIGURE 4. Percentage of efficacy patients achieving a therapeutic response during the initial and crossover esmolol titration periods, by esmolol dosage, in a multicenter, placebo-controlled, double-blind study. Cumulative percent is the number of responders at a given dosage or lower, divided by the number of efficacy patients (n = 61). Relative percent is the number of responders at a given dosage divided by the number of efficacy patients treated with that dosage.

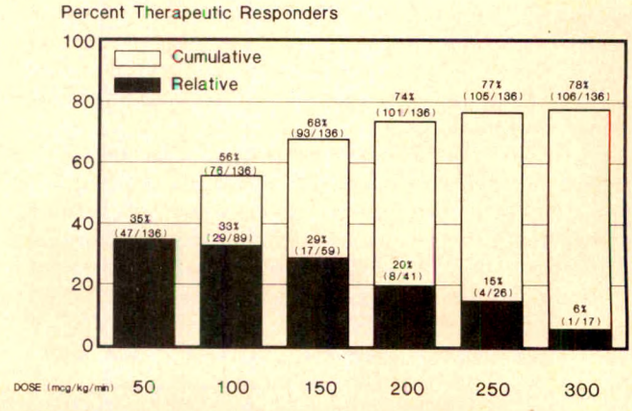

FIGURE 5. Percentage of efficacy patients achieving a therapeutic response during the titration period, by esmolol dosage, in an open-label, multicenter study. Cumulative percent is the number of responders at a given dosage or lower, divided by the number of efficacy patients (n = 136). Relative percent is the number of responders at a given dosage divided by the number of efficacy patients treated with that dosage.

TABLE IV Adverse Reactions Observed Among SVT Patients Treated with Esmolol (Infusion up to 24 Hours)

Body System/Adverse Reaction	(n)*	%†
Cardiovascular		
Hypotension	70	44
Symptomatic	(21)	(13)
Asymptomatic	(49)	(31)
Diaphoresis	16	10
Other	19	12

* Number of patients reported to have the respective adverse reaction.

† Total number of patients treated with esmolol = 160.

‡ Frequently, a single patient was reported to have more than 1 adverse reaction.

sion to normal sinus rhythm. In addition, esmolol exhibited a more rapid attenuation of its negative chronotropic effect after its termination compared with propranolol, which is a finding consistent with its ultrashort-acting pharmacokinetics. Therapeutic response in the 2 treatment groups was not influenced by differences in age (<65 vs ≥65 years), gender, type of SVT, primary diagnosis and postoperative status.

Although more esmolol patients developed asymptomatic hypotension (systolic blood pressure <90 mm Hg) than patients on propranolol, this hypotension largely caused no symptoms and no lasting adverse consequences. Hypotension occurred more frequently in the elderly and postoperative patient group with atrial fibrillation. In most patients (16 of 23), hypotension resolved within 30 minutes after discontinuation of esmolol. The fact that most patients responded to 50 to 150 μg/kg/min but were then advanced to higher doses (>200 μg/kg/min), which resulted in hypotension, suggests that hypotension might be avoided with more careful esmolol titration.

In a multicenter, double-blind, randomized, partial crossover study, esmolol (64%) was found to be more effective than placebo (8%) in the treatment of patients with SVT (Fig. 4).[10] In this study, most responders achieved response at doses of 50 to 150 μg/kg/min of esmolol. Further, it has been shown that in these patients, after discontinuation of esmolol, HR returned to preinfusion level within 30 minutes. This indicates that esmolol as used in the present study is similar to findings observed in a placebo-controlled study. In a multicenter, open-label study, esmolol infused for durations up to 24 hours was found to be effective and well tolerated in patients with SVT (Fig. 5).[11] The average dose of esmolol among responders was 97.2 ± 5.5 μg/kg/min. In most responders (90%), therapeutic response was sustained during the maintenance period and the response rate was similar among patients with atrial fibrillation, atrial flutter, sinus tachycardia and other types of SVT. Although the incidence of hypotension (symptomatic, 13% and asymptomatic, 31%) was more frequent than other adverse reactions among patients infused for durations of up to 24 hours (Table IV), in most of these patients (92%) hypotension resolved either during esmolol infusion or 30 minutes after discontinuation of esmolol. Thus these results are similar to the findings of the present study.

Esmolol has other potential applications that have been studied to date, including its effect on decreasing ischemic necrosis as shown by a reperfusion myocardial infarction study in dogs.[12] Its use in anesthesia to decrease HR acceleration and to control postoperative tachycardia has also been reported.[13,14] Its potential role in the treatment of acute hypertensive emergencies and in the management of ventricular arrhythmias is yet to be fully explored. These data suggest that esmolol deserves further trial in patients with unstable cardiovascular states, particularly because of its potency and the fast elimination of the β-blocking effects when its infusion is discontinued.

Discussion

Dr. Iskandrian (Philadelphia, Pennsylvania): Dr. Morganroth, hypotension in the postoperative patient is always a problem by itself. These patients have several IV lines running and their fluid balance is generally not good. I would like to know: Was there anything unusual about these patients who had hypotension? Were they postoperative patients? Was their left ventricular function compromised? Was an attempt made to titrate the dose down and continue the infusion at the lower rate? Was the hypotension observed without an effect on the rate, or was it a concomitant effect with the rate changes?

Dr. Morganroth (Philadelphia, Pennsylvania): One of the deficits of doing a controlled study, particularly a double-blind study involving many centers, is that one doesn't have the flexibility of acting in an open fashion. So the answers to most of your questions are no, because we didn't have the luxury of being able to have the patients' doses of esmolol titrated down or up, depending on a clinical response. It was all rigidly controlled by protocol by a study nurse in order to justify the pooling of multicenter data. I do not have any information regarding the data in this study relative to what percentage of the patients with asymptomatic hyotension would have had just as good an efficacy endpoint at, say, a 50 μg/kg/min decrease of their infusion, which is what you suggest. I have no doubt that would occur, which is suggested from just looking at the distribution of patients in the various groups where adverse effects occur. In terms of whether there was anything special about that group—were they closer to being right out of the operating room or were there any other factors that could be identified—the answer is no. Unfortunately, we do not have very precise measurements. For example, ejection fraction data per se on these patients are not available, so we could not identify any specific factor.

Dr. Gray (Los Angeles, California): I might be able to provide a partial answer to your question. We participated in an open-label supraventricular tachyarrhythmia study, in which all our patients were postoperative. The results were published in the June 1985 Journal of the American College of Cardiology. There were 24 patients and we used a similar protocol, except that it was an open-label, 1-drug study with no comparison. We had virtually the same incidence of hypotension as an adverse effect in which the substrate was the same—atrial fibrillation and some sinus tachycardia. Of our 12 patients who experienced hypotension, all but 2 could be continued on the drug by lowering the dose. In other words, we could wean back the dosage, maintain heart rate control to a reasonable extent and avoid the hypotension. In 2 patients we did have to discontinue the drug because of hypotension. In this particular study population, on average, the ejection fraction was in the low-normal range. There were patients who were in the decidedly abnormal range and some were in the clearly normal range. So, like all the other clinical work here, it is a mixture of things. My impression is that in patients who are fluid-depleted, or who have potential for subclinical fluid depletion, that is a factor related to hypotension. For instance, giving concomitant intravenous fluid challenge will sometimes raise the blood pressure and allow you to continue the dose of esmolol at the same level. But, by and large, we would first titrate back the dose of esmolol.

Dr. Morganroth: I think what we have learned this morning from the clinical pharmacology data was that peripheral vascular resistance does not increase on esmolol; therefore, esmolol is not a vasodilator. At least esmolol does not increase peripheral resistance; therefore, volume is going to be an important issue in these patients versus propranolol, in which one would expect some peripheral resistance to help compensate for a lowering of blood pressure. With esmolol, one won't have that compensation, and a fluid challenge may be the best first treatment, perhaps with some simultaneous decrease in the esmolol dose.

Dr. Kirshenbaum (Boston, Massachusetts): Thirty percent of the patients had coronary artery disease, at least as a label, presumably because they had a history of angina or a history of prior infarctions. Were any of them actively ischemic at the time they received the drug and had the tachycardia?

Dr. Morganroth: No, that would be an exclusion criterion for a protocol such as this, because one would want to treat active ischemia, particularly in an intensive care unit. I can only speak for my own patients, but it presumably holds for all the other investigators that none of the patients would have had either any obvious ischemia by any criteria, or, in fact, anything that would require immediate treatment, such as ventricular arrhythmias—nonsustained ventricular tachycardia, for example.

Dr. Kirshenbaum: In your off-drug heart rate response, at 20 minutes the esmolol population was still roughly 20% below their baseline heart rate. Is this because some of them had converted to a sinus rhythm and, therefore, would not return to the tachycardia? Or was it that, if you had waited 40 minutes or an hour, you would have seen them return to their baseline tachyarrhythmia?

Dr. Morganroth: I think there are multifactorial reasons why the esmolol patients' heart rates were still not back to baseline, after a few half-lives had passed. The reason is that after their acute arrhythmia is identified and IV lines are begun, they are asked to sign a consent form and they are watched by several people. I would postulate that their catecholamine levels are relatively high because they are frightened. After 1 or 2 hours—or actually up to 4 hours in most patients—they settle down and, therefore, their heart rate is as if they had been on placebo the entire time. If we had a placebo group, I would suspect that the esmolol group at 20 minutes would be identical to a placebo group.

Dr. Reves (Durham, North Carolina): Was there any difference in the degree of hypotension among centers? This gets at the point again about sympathetic tone; postoperatively, I know there is a lot of differene in the emergence from various anesthetic regimens that, I doubt, were controlled in this.

Dr. Morganroth: No, anesthetic regimens were not controlled among the centers.

Dr. Lee (McGaw Park, Illinois): A point of clarification: You mentioned you had 4 patients with symptomatic hypotension that had to be discontinued from study. You also mentioned 15 patients that were prematurely terminated because of hypotension. Could you clarify this?

Dr. Morganroth: Those 15 included the 4 who were terminated early because of symptomatic hypotension. They also included many of the patients who were terminated because of reaching a blood pressure of 90 mm Hg, and the physician said, well, that's good enough, let's stop the patient at this point. Obviously, in the clinical setting there would be no reason not to have continued many of these patients on esmolol and, whether given fluid or not, they would have done perfectly well. So, premature discontinuation of esmolol does not necessarily mean it was done for medically necessary reasons. It was more for study protocol reasons.

Dr. Lee: As you know, we are doing a study now comparing esmolol with verapamil in supraventricular tachyarrhythmia, and this is a hypothetical question because I don't know the answer yet as to how the study is going. But, if we assume that esmolol was as effective as verapamil in this study in terms of lowering ventricular rate, would you view esmolol as a possible agent to use before verapamil because of its short half-life? Would you use esmolol first, for example, and then if it didn't work, use verapamil?

Dr. Morganroth: This is a very good question. I think it was addressed a little bit by Allan Greenspan this morning. The question is, if as a physician I have a patient with supraventricular tachycardia and I have 2 drugs I could reach for on the shelf, one being esmolol and one being verapamil, which would I choose first? I think in this kind of population, I would have no hesitancy to argue that esmolol should be reached for first, for a very simple reason. I suspect verapamil is more potent compared with esmolol in terms of suppressing atrioventricular nodal conduction. Therefore, if I have a patient and I am not quite sure of how the left ventricle is going to react to the 2 drugs, I would much rather pick a drug with a very short half-life, such as esmolol, rather than verapamil, which has a much longer half-life. Then, if esmolol doesn't work, I would probably have no reason to hesitate using a smaller dose of verapamil to add to esmolol. The combination of these 2 drugs in the refractory patient—which should be uncommon—might be very useful, but the dose of verapamil would have to be kept very small.

Experimental and Clinical Observations on the Efficacy of Esmolol in Myocardial Ischemia

ROBERT A. KLONER, MD, PhD, JAMES KIRSHENBAUM, MD, RUDIGER LANGE, MD, ELLIOTT M. ANTMAN, MD, and EUGENE BRAUNWALD, MD

Beta blockers reduce myocardial oxygen demand and are therefore useful in ischemic states. They reduce angina pectoris and reduce the risk of death when administered long-term after acute myocardial infarction. Some studies suggest that when administered early after coronary occlusion they can reduce myocardial infarct size. Relative contraindications to β blockers, such as a history of congestive heart failure, chronic obstructive lung disease, atrioventricular conduction defects and low blood pressure, limit their use. Conventional β blockers have a relatively long duration of action and are either contraindicated or must be used with particular caution in patients with these contraindications. Esmolol is an ultrashort-acting β blocker with a biologic half-life of 9 minutes. Therefore, such an agent may be useful in patients with ischemic heart disease in whom reducing heart rate would be beneficial but in whom there is concern that β blockers might not be tolerated. Esmolol reduced myocardial infarct size in 2 experimental studies of coronary occlusion followed by reperfusion, and improved the recovery of the stunned myocardium when administered during experimental myocardial ischemia. Esmolol's brief duration of action may make it safer than conventional β blockers for the management of patients with unstable angina or myocardial infarction.

(Am J Cardiol 1985;56:40F–48F)

Experimental and clinical studies confirm that β-adrenergic blockers have beneficial effects during myocardial ischemia.[1] Beta blockers are useful in treating angina pectoris[2–4] and have been shown to reduce mortality when administered long-term to patients who have recovered from myocardial infarction.[5–7] Whether the acute administration of β blockers is capable of reducing myocardial infarct size remains controversial. Some experimental and clinical studies have shown that β blockers do reduce myocardial infarct size,[8] while others have failed to show this effect.[1,9] Nevertheless, β blockade remains an important means by which to reduce myocardial oxygen demand and thereby diminish ischemia in the setting of unstable angina, chronic stable angina and angina pectoris occurring after myocardial infarction. However, because β blockers have the potential for exacerbating congestive heart failure, for impairing conduction, for reducing blood pressure and for precipitating bronchospasm, they are not used in some patients, especially during the periinfarction period.

In recent studies, 18 to 28% of postinfarct patients could not receive β blockade because of the presence of absolute or relative contraindications.[5–7] The potential advantage of an ultrashort-acting β-blocking agent is that it can be administered to patients who could potentially benefit from a reduction in myocardial oxygen demand, but who may not be able to tolerate β blockade. The short biologic half-life (9 minutes) of esmolol allows this drug to be administered to such patients, with the knowledge that if they cannot tolerate β blockade, the effects of the drug are rapidly reversed by simply discontinuing the infusion.[10]

Experimental Studies of Conventional Beta Blockade in Ischemic Heart Disease

There is substantial experimental evidence that β blockers protect ischemic myocardium.[1] The ability of these agents to reduce actual ischemic cell death, however, remains controversial. Dog studies showed that propranolol and practolol reduced epicardial and precordial ST-segment elevation consequent to occlusion of the left anterior descending coronary artery.[11–14] Hillis et al[15] showed that pretreatment with propranolol significantly blunted the rise in intramyocardial P_{CO_2} (a measure of myocardial ischemia[16]) after coronary occlusion, suggesting that β blockade reduced the severity of ischemia. Goodlet et al[17] demonstrated that

propranolol infused directly into an ischemic area of myocardium preserves high-energy phosphate levels. In addition, propranolol has been shown to reduce the ultrastructural changes that occur during the first few hours of coronary occlusion, including the extent of mitochondrial swelling,[18] and extent of microvascular injury.[19] Possible mechanisms of action are shown in Table I.

Studies that have assessed the ability of β blockers to reduce the extent of ischemic cell death after coronary artery occlusion have shown mixed results. Maroko et al[12] showed that for similar degrees of epicardial ST-segment elevation 15 minutes after occlusion but before treatment, animals receiving propranolol had less depletion of creatine kinase activity at 24 hours. In other experimental studies, propranolol was shown to reduce the extent of necrosis estimated from loss of electrocardiographic R waves and development of Q waves,[20] and in others to reduce infarct size as assessed by pathology.[21] Miura et al[22] suggested that the ability of a β blocker to reduce infarct size was highly dependent on the time at which the agent was administered in relation to coronary occlusion. Thus, while pretreatment with β blockade reduced infarct size by 53%, when β blockade was administered 3 hours after occlusion, the reduction of infarct size was 28%, and when administered 6 hours after coronary occlusion, no effects were observed.[22]

However, there have been a number of studies in which β blockade was shown to have *no* beneficial effect on myocardial infarct size. For example, Cheng et al[23] showed that pretreatment with propranolol had no effect on infarct size in primates with 2 hours of coronary occlusion and reperfusion, while Reimer and Jennings observed that propranolol failed to reduce the extent of necrosis in dogs when the coronary occlusion was maintained for 3 hours followed by reperfusion.[24] Peter et al[25] also showed no benefit of propranolol on experimentally produced infarcts. Lange et al[26] showed that metoprolol and pindolol failed to reduce infarct size in a permanent coronary artery occlusion model in which the "area at risk" of developing necrosis was measured with radioactive microspheres. Reynolds et al[27] also showed that β blockade was ineffective in reducing the size of experimentally induced myocardial infarcts in the dog with permanent coronary artery occlusion, but was effective in reducing infarct size when 1 hour of coronary occlusion was followed by reperfusion.

The reason for the discrepancies in the results among the various studies showing a beneficial effect versus those showing no effect of β blockers on infarct size remains to be elucidated. One possibility is that β blockers, by reducing the myocardial oxygen demand, only *delay* the death of ischemic cells. If reperfusion is carried out early enough, at a time when treated cells are still viable (because the drugs have delayed cell death), then β blockers may reduce infarct size. If on the other hand, reperfusion is not instituted at all or is initiated too late, then eventually all cells destined to undergo ischemic cell death do so, and β blockers fail to reduce infarct size.

TABLE I Possible Mechanisms of Action by Which Beta Blockers Reduce Ischemic Injury

*	Reduction of myocardial oxygen consumption by blockade of β-adrenergic receptors (decreased heart rate and contractility)
	Decreased lipolysis and myocardial free fatty acid uptake shifting utilization of myocardial substrate to glucose
	Redistribution of coronary collateral flow toward the more ischemic subendocardium
†	Shifting the O_2-hemoglobin dissociation curve to the right
†	Direct membrane-stabilizing effect
†	Alteration of platelet function

* Principal mechanism of action.
† Mechanism of little or no importance.

Experimental Observations on the Effects of Esmolol

Effect of esmolol on experimental myocardial infarct size: Lange[28] studied the ultrashort-acting β blocker esmolol in dogs subjected to a 3-hour experimental occlusion of the left anterior descending artery followed by 3 hours of coronary reperfusion. Treated dogs received a continuous infusion of esmolol, begun 15 minutes after coronary occlusion, with the dose titrated to reduce heart rate by 20% (100 to 150 μg/kg/min). The "area at risk" determined in vivo was similar in both groups. In control animals, 73 ± 6% of the ischemic area at risk became necrotic, while in treated animals only 48 ± 7% became necrotic ($p < 0.025$). While untreated animals showed a deterioration in cardiac function in the early phases of reperfusion, no such deterioration of function occurred in the esmolol-treated group. Lange's investigation confirmed and extended a study by Zaroslinski et al,[10] which showed that esmolol reduced infarct size when coronary occlusion was maintained for 1 hour followed by 1 day of coronary reperfusion.

Therefore, in a coronary reperfusion model, esmolol reduced myocardial infarct size and prevented early functional deterioration after coronary artery reperfusion.

Effect of esmolol on stunned myocardium in experimentally induced myocardial ischemia: Recent experimental studies have shown that brief periods of transient coronary occlusion followed by reperfusion, in which no necrosis develops, can result in relatively prolonged depression of regional function, cardiac ultrastructure and high-energy phosphate levels. This phenomenon has been referred to as stunning of the myocardium.[29] It occurs not only in experimental models of acute ischemia,[30–32] but may also occur in patients with unstable angina[33] and in those with multivessel coronary artery disease who develop exercise-induced angina.[34] Postischemic depression of ventricular function, i.e., myocardial stunning, may also occur in some patients who receive thrombolytic therapy for acute myocardial infarction in whom there is little or no immediate return of cardiac function following reperfusion, but in whom function is improved 10 to 14 days after reperfusion.[35]

Three of the coauthors carried out an investigation (presented in part at the annual meeting of the American College of Cardiology, 1983[36]) designed to determine whether esmolol enhances functional recovery when given before and during brief coronary occlu-

sion. Sodium pentobarbital-anesthetized open-chest dogs were intubated and mechanically ventilated. Heart rate and arterial pressure were recorded and the left ventricle was instrumented with ultrasonic crystals in order to measure the percent systolic shortening of regional myocardial segments. The proximal left anterior descending coronary artery was occluded with a Schwartz atraumatic vascular clamp for 15 minutes, followed by 4 hours of reperfusion induced by abruptly removing the clamp. This period of ischemia has been shown to be too brief to induce tissue necrosis, but does mimic severe coronary spasm in man. Twelve dogs received esmolol (100 to 150 μg/kg/min) commencing 1 hour before the occlusion and ending at the onset of reperfusion, while 12 control dogs received saline. Regional myocardial blood flow was measured 10 minutes after coronary occlusion.

With coronary occlusion, there was an increase in left ventricular (LV) end-diastolic pressure in both groups (Fig. 1). With esmolol infusion, heart rate fell from 147 to 122 beats/min ($p < 0.001$) and remained significantly lower than in the control dogs during the coronary occlusion. Following reperfusion, heart rate in control and treated groups was similar, confirming that β blockade is rapidly terminated after esmolol infusion is discontinued.

LV end-diastolic pressure tended to be lower during the reperfusion phase in the dogs that had received esmolol, although this difference was not significant.

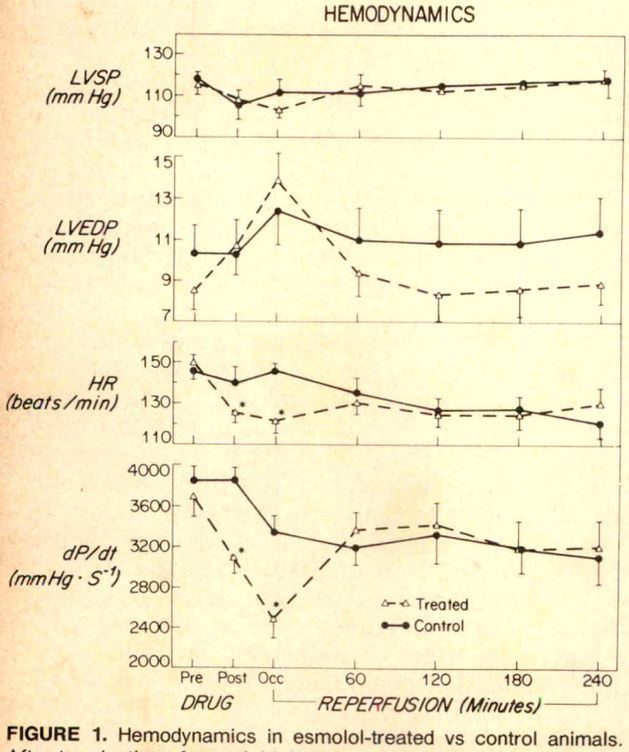

FIGURE 1. Hemodynamics in esmolol-treated vs control animals. After termination of esmolol infusion at reperfusion, heart rate (HR) and dP/dt come back to baseline during the remainder of the experiment. LVSP = left ventricular systolic pressure; LVEDP = LV end-diastolic pressure; dP/dt = change in pressure over change in time. Pre = pre-drug therapy; Post = post-drug; OCC = occlusion.

There was a significant fall in dP/dt during the infusion of esmolol and the fall in dP/dt during coronary occlusion was greater in the treated than in the control group (Fig. 1). Upon coronary reperfusion and termination of esmolol infusion, dP/dt in the control and treated groups was similar, confirming esmolol's short half-life.

Typical waveforms of subendocardial segmental wall motion from a control animal and an esmolol-treated animal are shown in Figure 2. In both groups, preocclusion waveform morphology showed active contraction (segment shortening) as demonstrated by a reduction in the distance between crystals during systole (downward deflection on the tracing). After 15 minutes of coronary occlusion the ischemic myocardial segments bulged paradoxically during systole. After 4 hours of reperfusion, systolic bulging was less intense, but was still present in the control dog. In contrast, the dog that had been treated with esmolol during occlusion showed active contraction during the reperfusion phase.

The extent of systolic shortening of the subendocardium in control and esmolol-treated animals is compared in Figure 3. Before coronary occlusion, systolic shortening was positive, reflecting active contraction. During coronary occlusion, systolic shortening became negative; i.e., paradoxical bulging occurred. Upon reperfusion, there was some recovery in both groups; but after 4 hours of reperfusion in controls there was, on the average, still no active contraction, indicating severe stunning of the myocardium. In contrast, systolic shortening did occur in animals that had received esmolol. In control animals, recovery of subendocardial wall motion was only 8% of preocclusion value, while in esmolol-treated animals recovery was 48% ($p < 0.05$). Although improved recovery was observed with esmolol in the subendocardium, the degree of recovery in the subepicardial tissue did not differ between groups.

There was a trend, which was not statistically significant, for regional myocardial blood flow to be lower in the esmolol-treated group in both ischemic and nonischemic subepicardium and subendocardium (Fig. 4). These findings suggest that the beneficial hemody-

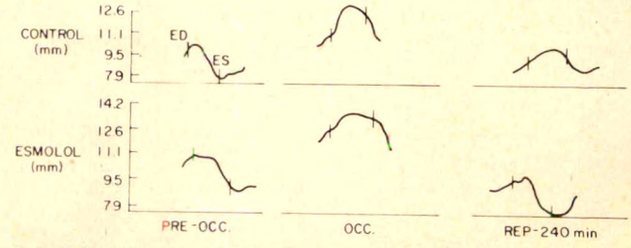

FIGURE 2. Waveform tracings show segment length between a pair of ultrasonic crystals within the ischemic zone of a control vs esmolol-treated animal. Vertical markings represent end-diastole (ED) and end-systole (ES). Preocclusion (PRE-OCC.), the left ventricular segment shortens during systole in both animals; during coronary occlusion (OCC.) there is paradoxical systolic bulging in both animals. With reperfusion (REP) there is active shortening in the esmolol-treated animal; paradoxical bulging persists in the control animal (stunned myocardium).

namic effects of esmolol during the reperfusion phase were not due to greater blood flow during coronary occlusion.

Thus, in the anesthetized open-chest dog with transient myocardial ischemia, esmolol reduced heart rate significantly, an action that was rapidly reversed upon termination of esmolol infusion. Esmolol also accelerated postischemic recovery of reperfused, stunned subendocardium.

Clinical Studies of Beta Blockers in Ischemic Heart Disease

Beta blockers are now widely used for the treatment of angina pectoris, and several studies have shown that they reduce the frequency of angina and increase the threshold for the development of angina.[2–4] In addition, β blockade increases the threshold for developing angina pectoris, even in those patients whose heart rate is maintained constant by atrial pacing.[37]

When administered to patients with acute myocardial infarction, β blockers have been shown to reduce heart rate, arterial pressure and cardiac output with small and variable changes in LV filling pressures;[38–40] in addition they narrow the arterial-coronary sinus oxygen difference and lessen myocardial lactate production.[38] Mueller et al[40] showed that in patients without contraindications to β blockade, propranolol reduces myocardial oxygen consumption and does not cause large increases in pulmonary capillary wedge pressure. Propranolol reduces plasma catecholamine concentrations during evolution of infarction and shifts the metabolism from that of free fatty acids to carbohydrates.[38,41]

Several clinical studies have shown that β blockade is capable of reducing ST-segment elevation during myocardial infarction;[39,42,43] in addition, Waagstein and Hjalmarson demonstrated that these agents reduce ischemic chest pain during infarction.[44]

Clinical studies that have assessed the ability of β blockers to reduce myocardial infarct size have provided mixed results, not dissimilar to experimental results. Yusef et al[45] reported that intravenous atenolol administered during the early phase of infarction reduced MB-CK release. Early administration of metoprolol, alprenolol or timolol has been shown to reduce infarct size, estimated by enzymatic techniques or QRS analysis.[8,46–48] Peter et al[49] reported that patients treated with propranolol within 4 hours of onset of symptoms had lower peak CK values and less cumulative CK appearance. Norris et al[50] showed that propranolol reduced the incidence of threatened myocardial infarction.

On the other hand, there have been several studies in which β blockers had no effect on myocardial infarct size in humans. A large multicenter study to assess the effect of propranolol on infarct size, measured by both enzymatic technique and electrocardiographic QRS mapping, showed no beneficial effect;[9] however, in this study, patients did not receive the β blocker until an average of more than 8 hours after symptoms—a time at which it may have been too late for propranolol to have either delayed cell death or salvaged tissue. Johansonn[51] studied the effects of 1 dose of intravenous practolol followed by oral atenolol in patients with acute myocardial infarction and found no difference in peak CK elevations or ST elevations.

There is less dispute about the efficacy of β blockers in the post–myocardial infarction patient. There have been several recent well-controlled clinical trials that have shown that when β blockers are administered chronically after acute myocardial infarction, long-term mortality is reduced.[5–7] Results from 3 of these

studies are summarized in Table II. The mechanism of action by which β blockers reduce long-term mortality is under investigation. In the Beta-Blocker Heart Attack Trial,[7] propranolol was begun 5 to 21 days after infarction. Hence, reduced mortality in this study could not have been related to any beneficial effect on myocardial infarct size. It appears that β blockers may reduce incidence of ventricular arrhythmias in the chronic phase of infarction;[52] they reduce the incidence of sudden death and of reinfarction, and it is also possible that they protect the myocardium against further episodes of ischemia or infarction. The results of these clinical studies are clear enough to warrant treatment with β blockers of patients who have suffered acute myocardial infarction and who have no contraindications to this type of therapy.

In summary, β blockers are useful for the treatment of angina pectoris and appear to exert beneficial effects in patients with acute myocardial infarction—including reduced oxygen demand, reduced mortality and, in some studies, reduced infarct size as well.

Effect of Esmolol in Patients with Acute Myocardial Ischemic Syndromes

The relatively long durations of actions of currently available β blockers raise concern about the use of these agents in certain subgroups of patients with acute ischemia or infarction. These include patients with LV dysfunction in whom there is concern that severe heart failure may be precipitated; patients with slightly prolonged PR intervals in whom there is concern of precipitating further atrioventricular block; patients with a history of smoking or chronic obstructive lung disease in whom there is concern of precipitating bronchospasm; and patients whose blood pressure is on the low side of normal in whom there is concern of precipitating hypotension. The risk of developing these complications may limit the use of β blockers in the very patients in whom reduction of oxygen demand would be most useful. Because the duration of action of esmolol is only minutes, patients may receive this drug with relative safety; if adverse effects develop, the drug can simply be stopped and the adverse effects rapidly reversed. This is not the case with conventional β blockers, which require several hours to dissipate. Kirshenbaum et al[53] recently reported the results of a study in which the safety and efficacy of esmolol in lowering the ventricular rate was determined in patients with myocardial ischemia. The study group consisted of 5 patients with acute myocardial infarction, 10 patients with post–myocardial infarct angina and 4 patients with unstable angina, all of whom had a heart rate >60 beats/min. After baseline hemodynamic measurements, esmolol was administered in maximum doses of 300 μg/kg/min and infused for up to 420 min. Heart rate fell from 92 ± 11 (mean ± standard deviation) to 77 ± 13 beats/min ($p < 0.01$), and systolic arterial pressure fell from 120 ± 13 to 97 ± 11 mm Hg ($p < 0.01$) during the initial 30-minute infusion period, and these parameters remained significantly reduced throughout the infusion. Thirty minutes after terminating the infusion of esmolol, heart rate returned to within 4% of baseline values and mean arterial pressure to within 6% of baseline values. During esmolol infusion, there was no statistically significant increase of pulmonary capillary wedge pressure or PR interval. All 5 patients who required early termination of infusion because of systolic blood pressure falling below 90 mm Hg recovered within 30 minutes of stopping esmolol.

No patient developed symptomatic bronchospasm or initiation or exacerbation of congestive heart failure. No patient developed atrioventricular conduction abnormalities while on esmolol. Fourteen patients who completed the maintenance infusion of esmolol

were started on conventional oral β blockers. All patients tolerated oral β blockers without developing symptomatic adverse reactions.

The results of this study suggest that esmolol is safe and effective in lowering heart rate and arterial pressure (and hence rate-pressure product) in patients with acute myocardial ischemia and infarction and that the hemodynamic effects are rapidly reversed after termination of the infusion. In patients with acute ischemia in whom there is a desire to reduce oxygen demand, but concern that β blockade may precipitate heart failure, bronchospasm, conduction abnormalities or hypotension, esmolol may be safer to use than conventional longer-acting β blockers.

In summary, β blockers have been shown to be beneficial in the treatment of acute myocardial ischemia and have been shown to reduce mortality when administered long-term after acute myocardial infarction. Their effect on myocardial infarct size remains controversial. The ultrashort-acting β blocker esmolol may be an ideal drug to use in patients with myocardial ischemia in whom a reduction of heart rate is desirable but in whom there is concern that β blockers might not be tolerated. This agent has been shown to reduce experimental myocardial infarct size in reperfusion protocols and to improve recovery of the stunned myocardium. Clinical studies suggest that esmolol is effective in reducing heart rate of patients with ischemia and that its effect on heart rate is rapidly reversed after termination of drug infusion.

Discussion

Dr. Sonnenblick (Bronx, New York): I might ask you the first question. Might you be mixing 2 endpoints? One is infarct size and the other is whether one can subdue active ongoing ischemia, such as unstable angina? The MILIS study was quite negative and I think very disappointing, and even the metoprolol repeat MIAMI study came out negative. In the face of that, one has to worry about being able to reduce infarct size metabolically. On the other hand, I do not think there is much argument among most people that unstable angina, when stabilized, has probably saved some myocardium basically by avoiding an impending infarction. With that in mind, did you see a clinical benefit in that patients had less chest pain and electrocardiographic changes than occurred during an unstable state? In other words, it is nice to have a decrease in heart rate and blood pressure, and if it is tolerated safely, I think that is a very nice benefit. However, was there a clinical benefit of esmolol that you could say was easily demonstrable either by chest pain, electrocardiographic changes or your clinical assessment of the patient?

Dr. Kirshenbaum (Boston, Massachusetts): In this preliminary study, clinical efficacy as determined by either a reduction in infarct size or a decrease in frequency or severity of ischemic episodes was not specifically measured. However, our impression was that esmolol did in fact provide a clinical benefit to the patients. We had 8 patients on intravenous nitroglycerin at the initiation of the β blockade because they had episodes of chest pain during the preceding 24 hours. In 6 of those 8 we had to terminate the intravenous nitroglycerin during the esmolol infusion because of the blood pressure response. None of these 6 patients had subsequent ischemic events during the esmolol infusion. At the end of the study when we turned the esmolol off, only 1 of those patients went on to have another episode of chest pain requiring reinstitution of intravenous nitroglycerin. All of these 8 patients were started on oral β blockers. In all 19 patients, only 2 had esmolol discontinued because of hypotension associated with an acute ischemic event. One patient had an evolving acute anterior myocardial infarction; the other patient developed a postprandial vagal eqisode associated with a fall in blood pressure and angina. I have no data on the frequency of ischemic events in the hours immediately before esmolol infusion and so I cannot comment on whether esmolol actually caused a reduction in the number of ischemic events. But at least in the 19 patients, the vast majority had no ischemic episodes during their esmolol infusion. In 1 patient, in fact, who had the esmolol terminated according to protocol and metoprolol started, there was a delay in starting the metoprolol between the house officer writing the order and the nurse fulfilling it. During that time, the patient had an ischemic episode with acceleration of her heart rate. She had clear angina during that time. So it is clinically suggested that during esmolol we are preventing the increase in oxygen demand and that minimizes the episodes of ischemia. Thus, it is clinically suggested that esmolol's ability to lower myocardial oxygen demand via reduction in heart rate-blood pressure product has the potential for reducing angina.

Dr. Morganroth (Philadelphia, Pennsylvania): Because of this experience, do you now, or would you if you could, routinely use esmolol in every patient in the coronary care unit who has active ischemia? If not, in whom would you be more cautious with the agent except for the obvious issues of heart block or overt heart failure?

Dr. Kirshenbaum: If I had a patient with symptomatic ischemia with a resting heart rate >75 beats/min and systolic pressure >110 mm Hg in whom I felt augmented myocardial oxygen demand was contributing to angina, I think it would be prudent to begin esmolol.

Dr. Morganroth: Do you place all patients with asymptomatic infarction or uncomplicated infarction in their first day on intravenous β blockers?

Dr. Kirshenbaum: No.

Dr. Morganroth: None of them, or if some, which patients?

Dr. Kirshenbaum: The initiation of β blockade in the acute infarct setting where patients are asymptomatic is presumably going to be done to reduce infarct size or to prevent against further eqisodes of ischemia. The data supporting β blockers for infarct reduction are not yet firm; thus, we do not aggressively initiate such medication in an asymptomatic patient. On the other hand, the available evidence certainly supports the use of β blockers in post–myocardial infarction patients for prevention of subsequent myocardial infarctions or sudden death. Thus, we routinely place patients without contraindications during their early post–myocardial infarction recovery period on oral β blockers.

Dr. Morganroth: But, you know, the intravenous metoprolol data are such that those patients received the drug on admission, or as close to admission as possible, and they had a 90-day mortality rate that was clearly less than those who received placebo on admission.

Dr. Kirshenbaum: Yes, but that was not confirmed in the MIAMI data and their long-term mortality was no different whether the drug was given at the start or at the end of admission. I am not by any means trying to claim that esmolol or any of the β blockers are infarct-limiting.What is important in the metoprolol study is that 47% of the patients who came in were excluded by the study's entry criteria. In the 3 large post–myocardial infarction β-blocker trials, 18 to 20% of patients were excluded at the onset because of potential adverse reactions to β blockers. Now some of those people were excluded because their heart rates and blood pressures were already low; in others there was a fear of producing bronchospasm, atrioventricular block, etc. It is in this subset of patients that esmolol may be particularly useful in defining a cohort that could safely tolerate β blockers, despite a prior history of bronchospasm, conduction system disease, etc. The ability to tolerate esmolol could then select patients who could be safely started on longer acting β blockers. This would add β blockers' proven long-term preventive benefit to post–myocardial infarction patients who currently are routinely excluded from β blockers. If they

tolerate esmolol, they should tolerate an oral agent, and that hopefully is where esmolol is special.

Dr. Sonnenblick: In patients with unstable angina, with a large amount of myocardium at risk, do you think there is a subgroup in whom you could show that when giving the β blocker, you will find the end-diastolic pressure rising and the output decreasing, which indicates perhaps that the tachycardia is due to a huge infarct—as opposed to another group where if the filling pressure falls, you have showed a benefit on the ischemia and that you ought to press ahead more vigorously with a β blocker? Have you seen that differential?

Dr. Kirshenbaum: Our patient population was too small to prove this very logical assumption. I suspect most patients with severe unstable angina at rest have markedly diminished myocardial blood supply, secondary to fixed coronary obstruction, with concomitant coronary spasm or thrombosis, rather than acute increase in myocardial oxygen demand. However, if their instability is accompanied by persistent elevations in heart rate or blood pressure, then I strongly suspect that a reduction of myocardial oxygen demand would help alleviate angina.

Dr. Lowenthal (Philadelphia, Pennsylvania): In the clinically stable patient who has had a myocardial infarction and who has had a good response to esmolol, would you consider starting an oral β blocker during the maintenance period so that when the infusion has been discontinued, there will not be any risk of rebound and the patient will be adequately covered? Have you had that experience?

Dr. Kirshenbaum: We did not have that experience because all of our patients were started on oral agents following the termination of the esmolol. One patient had delay in receiving oral metoprolol after esmolol infusion and experienced an ischemic episode in the interim associated with tachycardia.

Dr. Lee (McGaw Park, Illinois): In the patients who became hypotensive, did the peripheral resistance decrease?

Dr. Kirshenbaum: While we did not calculate the peripheral resistance during the hypotensive episodes, I suspect it was lower. However, the relative contributions to the hypotension from a reduction in cardiac output versus a reduced peripheral resistance are unknown.

Dr. Lee: I think that's an important issue—whether they were hypotensive because of vasodilation or because of reduced cardiac output.

Dr. Sonnenblick: In the data that he showed, the cardiac output, if anything, with time was rising at the time the blood pressure was falling. That leaves you the resistance to work with, so that would imply that the resistance had fallen somewhat further. But you also have volume problems in these patients that are on nitroglycerin as well, so it is a complex problem. If there are no further questions, I want to thank Dr. Kirshenbaum. These are difficult experiments to do and he has opened a whole area—both infarct reduction and also the safe and effective way to acutely test the problem. Thank you.

Use of Esmolol in Hypertension After Cardiac Surgery

RICHARD J. GRAY, MD, TIMOTHY M. BATEMAN, MD, LAWRENCE S. C. CZER, MD, CAROLYN CONKLIN, BSN, and JACK M. MATLOFF, MD

Systolic hypertension, which is common soon after cardiac surgery, increases cardiac work and may threaten fresh vascular anastomoses. Because postoperative hypertension is often associated with elevated catecholamines and preoperative use of β-blocking agents, esmolol, an ultrashort-acting β-blocking agent, was compared with nitroprusside in a crossover study in this setting. Twelve patients, 18 to 28 hours after cardiac surgery (coronary artery bypass graft in 9, aortic valve replacement in 2 and valved aortic conduit with reimplantation of coronary arteries in 1 patient) received controlled infusions of esmolol (mean dosage 142 ± 100 μg/kg/min, range 50 to 300 μg/kg/min) and nitroprusside (mean dose 1.6 ± 1.3 μg/kg/min, range 0.5 to 2.75 μg/kg/min). In this open-label study, choice of the first drug was randomized, after which patients were then crossed over to the other study drug. Therapeutic response (≥15% systolic blood pressure reduction) was achieved in 11 of 12 esmolol patients and 12 of 12 nitroprusside patients. Both drugs significantly lowered systolic and diastolic blood pressure, as well as left ventricular stroke work index. While the cardiac index was decreased by esmolol and increased by nitroprusside, neither drug significantly changed stroke volume index. Systemic vascular resistance, unchanged by esmolol, was decreased significantly by nitroprusside. Oxygen saturation and Pao_2, unchanged with esmolol, were both significantly reduced with nitroprusside. Thus, for hypertension early after cardiac surgery, esmolol is safe, effective and rapid and, compared with nitroprusside, results in less unwanted decrease in diastolic blood pressure and oxygen saturation, but there is more decrease in heart rate and cardiac index.

(Am J Cardiol 1985;56:49F–56F)

Hypertension, occurring in the early hours after open heart surgery, is common and may be quite troublesome. Its occurrence is particularly untimely as fresh vascular anastomoses may be threatened, and increasing demands are placed on a myocardium just beginning to recover from ischemic insult. Even more serious complications may arise in the patient recognized at surgery to have an atherosclerotic, thin-walled, tenuous aorta or a recently repaired or coexistent aortic dissection. The clinical situation in these patients may be one of hyperdynamic circulation with increased heart rate and cardiac output. Very often systolic blood pressure elevations predominate with normal or even subnormal diastolic levels.

Patients rapidly and completely withdrawn from preoperative β-blocking agents, as well as those previously hypertensive, are particularly subject to this occurrence. The documentation of elevated circulating catecholamine levels early after open heart surgery has figured prominently in the proposed mechanism of this complication.[1–5] Many investigators have demonstrated a several-fold increase over preoperative levels of epinephrine, which may last for 2 to 3 days. Elevations of serum norepinephrine levels are less striking but may persist for several days postoperatively. It has also been suggested that extracardiac sympathetic activity may contribute to vasoconstriction or release of norephinephrine from postsynaptic junctions.[6] Alterations in serum renin and aldosterone levels have also been implicated but have been less completely studied.

Various definitions of postoperative hypertension have been used. Flaherty et al[7] suggested that a sudden and persistent increase in mean arterial pressure of 20 mm Hg or more, with a mean arterial blood pressure of at least 95 mm Hg, was indicative of this phenomenon, and found that 61% of patients undergoing coronary bypass surgery at their institution met this criterion. Fremes et al[8] proposed a mean arterial pressure of at least 105 mm Hg and 42% of their coronary bypass patients met this definition. Considering

that an estimated 191,000 bypass surgeries were performed in 1983,[9] one can appreciate the magnitude of this clinical problem.

Except in previously hypertensive persons, the natural history is usually a benign one, with gradual resolution of hypertension over the first 2 to 3 postoperative days. Because of its limited duration and the fact that, initially, patients requiring therapy are anesthetized, often intubated and unable to take oral medications, therapy is almost always intravenous. Some, but not all, patients must then be weaned to oral medications, which may be prescribed for several postoperative days. Initial therapy is most commonly sodium nitroprusside,[8] with recent interest in nitroglycerin.[7] Other intravenous antihypertensives, such as hydralazine, methyldopa and even chlorpromazine, are often used as well. Unfortunately, these agents are not well suited for treatment of systolic hypertension; in some cases they add to the tachycardia and hyperdynamic circulatory state and may produce hypoxemia. Beta-blocking agents have potential value, but have been used infrequently because of the traditional nonavailability of intravenous infusion and the relatively slow onset and offset of action, should adverse effects arise.

For these reasons, we compared esmolol, an ultrashort-acting β-blocking agent, and nitroprusside, the standard form of therapy for postoperative hypertension.

Methods

Patient selection: Systolic blood pressure of at least 140 mm Hg was required. We chose a systolic blood pressure criterion because systolic hypertension appears to predominate in this condition, and also because of inaccuracies known to exist in algorithms for determination of mean arterial blood pressure from analog signals. Additionally, patients had to be between 18 and 75 years old and able to give informed consent. All patients had to have a functioning balloon flotation catheter with pulmonary capillary wedge pressure <18 mm Hg. Heart rate had to be >70 beats/min and the cardiac index >2.2 liters/min/m^2, with a stroke volume index >25 ml/beat/m^2. Criteria for exclusion included pregnancy, atrioventricular block greater than first degree, sick sinus syndrome without a functioning pacemaker, chronic obstructive pulmonary disease severe enough to preclude the use of a β-blocking agent or active bronchospasm. In addition, patients receiving other experimental drugs within the past 2 weeks and those with significant impairment of renal or hepatic function were excluded.

Patient description: Twelve hypertensive patients, 5 men and 7 women, were studied. The mean arterial pressure before esmolol treatment was 103 mm Hg; before nitroprusside, it was 106 mm Hg. Average age was 65 ± 10 years (range 43 to 74). The cardiac surgical procedure consisted of isolated coronary bypass grafting in 9 patients, with aortic valve replacement in 2 patients, and insertion of a valved conduit replacement of the aortic root with reimplantation of the coronary arteries (the Bental procedure) in 1 patient.

Preoperatively, 6 patients had received β-blocking medications, and 6 had a history of preoperative hypertension. Preoperative left ventricular angiographic ejection fraction was 70 ± 22% and left ventricular end-diastolic pressure was 16 ± 3 mm Hg. The number of hours in the intensive care unit before study was 23 ± 3 hours.

Operative procedure: Anesthetic medications included intravenous Fentanyl and diazepam, with supplemental nitrous oxide and halothane as needed. Cardiopulmonary bypass was performed using a bubble oxygenator, and myocardial preservation used the technique of hypothermic, hyperkalemic cardioplegia. Mean cardiopulmonary bypass time was 140 ± 51 minutes, ischemic aortic cross-clamp time was 90 ± 43 minutes and the lowest esophogeal temperature achieved was 22 ± 2°C. The number of grafts inserted per patient was 3.5 ± 0.9.

Protocol: After identification of the patient and procurement of informed consent, a prestudy period was entered during which physical examination, medical history, blood and urinalysis as well as an electrocardiogram were obtained. If previously treated for postoperative hypertension, as was the case in all patients, medication was weaned and discontinued 20 minutes before beginning the study. Patients were then randomized to receive either esmolol or nitroprusside as their first treatment drug. After randomization, baseline hemodynamic and laboratory data were obtained. If randomized to esmolol, the first titration began with a loading infusion of 500 μg/kg/min for one-half minute. Following this, 25 μg/kg/min was administered for 4 minutes. Subsequent increases in titration dosage were at 50 μg/kg increments and were preceded by 1 full minute loading infusion. The maximum dosage allowed under this protocol was 300 μg/kg/min. If randomized to nitroprusside, the first titration began at a dosage of 0.5 μg/kg/min for 2 minutes. The second titration was at 0.75 μg/kg/min, but all subsequent increases in dosage were at 0.5 μg/kg/min increments. The maximal allowable dosage was 10 μg/kg/min.

TABLE I Postoperative Hypertension Study Results

	Esmolol			Nitroprusside		
	Baseline	Drug	Δ%	Baseline	Drug	Δ%
Blood pressure						
Systolic (mm Hg)	170 ± 12*	136 ± 14	−20%	173 ± 11*	141 ± 15	−18%
Diastolic (mm Hg)	69 ± 14*	63 ± 14	− 8%	72 ± 15*	50 ± 15	−31%
Heart rate (beats/min)	95 ± 9*	82 ± 11	−14%	97 ± 14*	104 ± 15	+7 %
Responders						
>15% SAP		11/12			12/12	
SAP ≤120 mm Hg		1/12			3/12	
DAP ≤50 mm Hg		1/12			7/12	

* p <0.05 baseline vs drug.
DAP = diastolic arterial pressure; SAP = systolic arterial pressure.

The titration period for each drug was ended when certain criteria had been met. Reaching either a 15% decrease in systolic arterial pressure or a systolic pressure of ≤120 mm Hg constituted efficacy criteria. Heart rate <60 beats/min, systolic arterial pressure <90 mm Hg or reaching the maximal allowable dosage of either drug constituted safety endpoints. After the treatment endpoints had been reached, repeat hemodynamic measurements were obtained after 20 minutes of steady-state infusion. A 20-minute washout period followed, and the patients were then crossed over to the other drug for a repeat of the titration sequence.

Data analysis: All data are reported as mean ± standard deviation. A paired *t* test analysis was performed to determine significant differences, which were deemed present when p values were <0.05.

Results

A summary of results is listed in Table I. Systolic arterial pressure was decreased with esmolol from 170 ± 12 to 136 ± 14 mm Hg, representing a 20% decrease. With nitroprusside, systolic pressure was decreased from 173 ± 11 to 141 ± 15 mm Hg, an 18% decrease. Both of these changes are statistically significant. Diastolic pressure with esmolol was reduced from 69 ± 14 to 63 ± 14 mm Hg, an 8% decrease, and with nitroprusside from 72 ± 15 to 50 ± 15, a 31% decrease, both of which are statistically significant. Heart rate with esmolol was reduced from 95 ± 9 to 82 ± 11 beats/min, a 14% decrease; in contrast, nitroprusside resulted in a 7% increase, from 97 ± 14 to 104 ± 15 beats/min. Eleven of 12 patients with esmolol, and all of the nitroprusside patients, met the 15% systolic arterial pressure reduction criterion, and therefore were responders. One of 12 esmolol patients and 3 of 12 nitroprusside patients achieved a systolic arterial pressure <120 mm Hg. Diastolic arterial pressure <50, possibly an adverse effect, was seen in 1 esmolol patient and 7 of 12 nitroprusside patients. The blood pressure and heart rate data are illustrated in Figure 1.

Figure 2 illustrates the dose-response relation with esmolol. At 25 μg/kg/min, 4 of 12 patients (33%) achieved the desired blood pressure response. At 100 μg/kg/min, 8 of 12 patients (66%) were cumulative responders. Two additional individual patients, 1 at 150 and the other at 200 μg/kg/min, respectively, were added to the cumulative responders, and at the maximal dosage level of 300 μg/kg/min, the last additional patient became a responder. These data suggest that control of hypertension with esmolol may require higher dosage levels. This is in contrast to the experience with esmolol in the treatment of supraventricular tachyarrhythmias, where most potential responders do so at the dosage of ≤150 μg/kg/min.[10]

Figure 3 illustrates the individual systolic blood pressure responses to various dosages of esmolol. Virtually all patient responses are consistent and predictable and further reductions in blood pressure occur with progressively higher esmolol dosage. Patient no. 11, at the top of the figure, was the only nonresponder to esmolol and appears to be identifiable because of the uniquely high blood pressure before therapy.

The effects of the 2 study drugs upon cardiac filling pressures are shown in Figure 4. In the left panel, right

Discussion

Dr. Lowenthal (Philadelphia, Pennsylvania): Dr. Gray, what was your mean level of PaO_2 reduction with the nitroprusside?

Dr. Gray (Los Angeles, California): The mean PaO_2 level went from 118 to 72 mm Hg.

Dr. Lowenthal: Would you postulate the mechanism to be shunting?

Dr. Gray: That's the general feeling. This finding has been demonstrated by many people, and the basic idea is that there is paralysis of the usual hemostatic control areas, so there is general paralysis of local precapillary regulation of blood flow.

Dr. Lowenthal: Do you think that is augmented at all through bypass and the various hookups during coronary artery bypass grafts?

Dr. Gray: I don't know whether there is the same degree of change, but this PaO_2 decrease has also been demonstrated in the intensive care setting with both medical intensive care unit patients and post–myocardial infarction patients who have been monitored hemodynamically. The decrease we showed may be more dramatic than in the intensive care unit patient, but is something that we encounter very often in the management of these patients. It is a reasonably serious and frequently noted phenomenon.

Dr. Lowenthal: Usually during the routine hypertensive encephalopathy, with no extracorporeal hookup, a substantial fall in PaO_2—say, from 100 to 70—is unusual. I don't know whether it is caused by the conversion to cyanide and thiocyanate. But, one of the hemodynamic spin-offs of this is whether or not the fall in PaO_2 could in part be related to the higher heart rate response that you see, and that it's not all a vascular effect of nitroprusside.

Dr. Gray: We measured oxygen delivery per pulse, and it also diminishes with nitroprusside so I don't think that's the explanation. I think we have to keep in mind that all the patient groups in which nitroprusside-induced hypoxemia has been documented have some element of cardiopulmonary/physiologic derangement. These are not people off the street with, as you say, a hypertensive encephalopathy or some noncardiopulmonary reaction.

Dr. Lowenthal: This is fascinating. Let me direct the next question to you, Dr. Reves, and we can discuss it. It is possible that this fall in PaO_2 could be due to blunting by the concomitant administration of trimethaphan with nitroprusside? That's been advocated in an attempt to block formation of the cyanide and thiocyanate.

Dr. Reves (Durham, North Carolina): Let me answer your first question about whether or not the drop in PaO_2 is related to cardiopulmonary bypass. I don't think it is. We just finished a study looking at shunt fractions immediately after bypass. We looked at the duration of bypass and all sorts of vasoactive compounds, and, in fact, sometimes a shunt fractioning improved after cardiopulmonary bypass. I think it's a real effect of sodium nitroprusside in this group of patients, the etiology of which I do not know. But I don't think the drop in PaO_2 is affected by cardiopulmonary bypass per se. Trimethaphan used to be the number 1 drug for postoperative hypertension, but I don't remember what happens to shunt data in those patients.

Dr. Sonnenblick (Bronx, New York): One of the questions I would ask is the problem of interpreting contractility or stroke work when you have the blood pressure falling. You might plot it as stroke volume versus pulmonary capillary wedge, because the fall in stroke work is going to be so dominated by the change in blood pressure that it doesn't really reflect the Starling-type curve that you're trying to plot. It would probably look somewhat the same, but it would be interesting to see what it looks like as a stroke volume plot.

Dr. Gray: It is obviously a question similar to the problem of the chicken and the egg—as the heart has less demand placed upon it because of the lower blood pressure, it's doing less work—but is it doing less work because it has been paralyzed in some way, or is it simply because the afterload is reduced?

Dr. Sonnenblick: I think the problem there is that you can change the work all over the lot by changing the blood pressure, independent of anything else, so it complicates the interpretation. You have got to remember the Sarnoff curves really were only stroke work curves, because blood pressure was held constant, so it's really a stroke volume curve with a constant blood pressure. As soon as you change the blood pressure, you can really make the curves move around significantly.

Dr. Gray: One can construct it here, just simply using the available data. The stroke volume with nitroprusside has absolutely no change. The wedge pressure falls from 14 to 10, so you would see a downward movement or one suggesting an improved functional status with nitroprusside, the traditional vasodilator response shifting to a new curve. The stroke volume index with esmolol has no statistically significant change, the number goes from 28 to 27 and the wedge pressure goes up a very small amount, from 13 to 14, so we would see a more or less static situation with regard to inotropic influence.

Dr. Sonnenblick: I would just like to extend another interpretation. Everything that you have shown says postbypass hypertension is a somewhat unique form of hyertension in that you really seem to have a cardiac-caused hypertension. In other words, you've got an increase in blood pressure that seems to be related to your cardiac output independent of the peripheral resistance. Is that perhaps related to the postperfusion hypothermia recovery period?

Dr. Gray: Well, I think the implication of your question is that we don't know what causes this hypertension. From interpreting our data, I would urge others to look at their own data in this regard; we don't normally expect to see a marked increase in systemic vascular resistance. In some patients, of course, it is quite high, there is no doubt about it. I don't want to imply that this drug is the only answer to this type of problem, because nitroprusside is better in some other patients. However, esmolol does seem to have kind of a mixed hemodynamic profile with very normal systemic re-

sistance, slightly elevated cardiac index, moderately high systolic blood pressure and relatively normal diastolic blood pressure.

Dr. Lowenthal: To support your contention, I think the fact that systemic resistance is basically normal and diastolic pressure is likewise normal, would tend to negate the contention that the renin angiotensin system is playing a major role here. Even though catecholamines may be elevated and innervention into the juxta-glomerular apparatus can stimulate renin production, it's probably not playing a major role.

Dr. Sonnenblick: So it rather supports the contention initially that the postoperative hypertension was caused by a catecholamine surge that was cardiac stimulating. It looks very much like the type of hypertension you get from stellate stimulation.

Dr. Gray: I don't have the results yet, but renin and epinephrine/norephinephrine levels were sent to the laboratory.

Dr. Iskandrian (Philadelphia, Pennsylvania): Was the pericardium left open, I assume, after the operation?

Dr. Gray: Our surgeons generally just open the pericardium in the inverted T and leave it open.

Dr. Iskandrian: That's fascinating; that's the first time we will see the effect on the intracardiac hemodynamics with an open pericardium. All the studies so far have been with intact pericardium. It is interesting that, even when the pericardium is open, you still see a slight elevation of the wedge pressure. One can only postulate that if the pericardium was not open, whether the elevation in wedge pressure would have been higher.

Dr. Lee (McGaw Park, Illinois): I am interested in your observation that the hypertension occurs within 1 or 2 hours after surgery. What is the time course of postbypass hypertension? Is it fairly stable and how long can one expect it to last?

Dr. Gray: This particular group of patients usually emerges from the operating room hypertensive, and all of our study patients were on some antihypertensive agent initially. However, because we have to get an informed consent, we did wait until the patient could give it to us. It might be argued that 24 hours later is still not a proper time to obtain a real informed consent on a patient, but that is the reality. So we have certain constraints. The patients were all studied on the average of 23 hours after the surgery, and the range is rather narrow—18 to 26, I think. At the end of the titration period, we made our recordings. We made a clinical decision at the end of the comparison as to what drug the patient should be put on, and in some patients it was esmolol, and in a few patients it was nitroprusside; mostly it was esmolol. We did treat the patients for anywhere from an hour and 10 minutes to 23 hours with esmolol—an average of just over 6 hours.

Dr. Morganroth (Philadelphia, Pennsylvania): What problems do you see with designing a protocol to clear up the confusion about the first 23 hours by actually having obtained informed consent before operation on all patients, and then allowing the anesthesiologist to start the drip of either nitroprusside or esmolol in the operating room? It seems to me that would be a more rigorous design to answer this question.

Dr. Gray: I see many problems. It would be very difficult to design such a protocol.

Perioperative Use of Esmolol

J. G. REVES, MD, and PAOLO FLEZZANI, MD

Stressful surgical stimuli, such as endotracheal intubation, surgical incision, organ manipulation and emergence from anesthesia, elicit adrenergic responses that precipitate transient but intense increases in heart rate and blood pressure. Although this response is well tolerated in healthy patients, patients with ischemic heart disease are at significant risk of myocardial ischemia and infarction owing to the sudden increase in myocardial oxygen demand. Parenteral β blockers are effective in blunting this adrenergic response, but the duration of action of these agents is long-lasting and the degree of β blockade is often difficult to predict. Further, long-acting parenteral β blockers may cause adverse effects, the reversal of which presents a difficult clinical problem in patients with ischemic heart disease. The availability of esmolol, an ultrashort-acting parenteral β-adrenergic antagonist with a half-life of 9 minutes, brings obvious advantages to the perioperative management of hypertension and tachycardia. With esmolol treatment, the difficulties of therapy with long-lasting β blockers are avoided. Also, to blunt the adrenergic response, the anesthesiologist will have an alternative to increasing the depth of anesthesia, which can accentuate cardiovascular depression and prolong awakening and postoperative respiratory depression. Clinical studies performed during the perioperative period reveal that esmolol is safe and effective in this setting. Esmolol has been shown to be safe and efficacious in patients in ASA classifications I through IV and patients undergoing carotid endarterectomy and coronary artery bypass surgery. The pharmacokinetic profile, rapid onset and elimination half-life make this agent particularly well suited to treat the very intense but transient adrenergic responses to surgical stress in patients undergoing cardiac and noncardiac surgery.

(Am J Cardiol 1985;56:57F–62F)

Esmolol is a fast-acting and ultrashort-lasting β_1-adrenergic antagonist[1] that has potential for use in the perioperative period. A drug that can quickly control tachycardia and minimize hypertension without prolonged negative chronotropic and inotropic effects is ideal for the treatment of transient episodes of hemodynamic hyperactivity that occur during anesthesia. Stressful stimuli such as endotracheal intubation, surgical incision and manipulation, cardiopulmonary bypass and emergence from anesthesia elicit adrenergic responses that cause transient increases in heart rate and blood pressure.[2] Although tachycardia and hypertension are well tolerated in most patients, they can lead to myocardial ischemia and myocardial damage in patients with ischemic heart disease undergoing cardiac surgery.[3]

The safe use of β-adrenergic antagonist drugs in the perioperative period is well established.[4] The continued administration of propranolol and other β-adrenergic antagonists is associated with less severe intraoperative hemodynamic instability[5–8] and continued administration avoids the potential hazards of abrupt withdrawal.[9] However, β-adrenergic antagonists can add to the effects of some anesthetics that also produce vasodilation, cardiac depression and decreased heart rate and interfere with normal homeostatic reflexes.[10–22] The availability of an effective but short-lasting β-adrenergic antagonist brings an obvious advantage in anesthetic management because it obviates the need to use either long-lasting β-adrenergic antagonists or the requirement to increase depth of anesthesia, which can accentuate cardiovascular depression and prolong awakening and postoperative respiratory depression. This is particularly a concern in short operations and when the stressful stimuli are brief. Advantages of esmolol compared with other parenteral β antagonists (propranolol and metoprolol) are predictability, rapid onset and short duration of action. Compared with the noncardioselective drug propranolol, a lower likelihood of development of postoperative hypertension secondary to unopposed α-receptor stimulation[23] is another potential advantage of esmolol.

TABLE I Esmolol During Anesthesia: Multicenter Studies

ASA class I–IV	185 patients	Safe, effective; attenuates tachycardia and hypertension during intubation
Carotid endarterectomy	74 patients	Safe, effective; attenuates tachycardia and hypertension during intubation
Coronary artery surgery	102 patients	Safe, effective; attenuates tachycardia and hypertension during intubation and surgical stress

ASA class I = no organic, physiologic, biochemical or psychiatric disorder; II = mild to moderate systemic disturbance or disease; III = severe systemic disturbance or disease; IV = life-threatening systemic disturbance or disease.

Laboratory Investigation

Dog studies have examined the effects of esmolol infusion with clinically relevant general anesthetic agents.[24,25] In dogs anesthetized with 2.2% end-expired enflurane (1 MAC), esmolol given for 20 minutes at infusion rates of 0, 100, 300, 1,000 and 3,000 μg/kg/min produced dose-related decreases in heart rate, left ventricular contractile force and blood pressure.[24] Decrements in contractile force were greater than heart rate, suggesting a more pronounced additive negative inotropic effect than negative chronotropic effect. Cardiac output was preserved until the highest doses of esmolol were given. Increases in heart rate after isoproterenol administration (1 μg/kg) were totally blocked with doses of 300 μg/kg/min of esmolol, yet blood pressure decreased, indicative of the β_1 selectivity of esmolol. Because β_1 blockade was complete at 300 μg/kg/min, but 1 dog died at 1,000 μg/kg/min and the other 4 dogs at 3,000 μg/kg/min, the safety margin appears to be relatively small in the enflurane-anesthetized dogs given esmolol. This is consistent with other data that show that enflurane and a β-adrenergic blocker (propranolol)[14] are a potent negative inotropic combination. However, enflurane appears to produce no greater hypotensive effect than halothane when both are combined with esmolol.[25] The hemodynamic depression caused by esmolol is significantly enhanced by inhalation anesthetics; both halothane (1.5%) and enflurane (2.2%) produced marked hypotension compared with esmolol in the same awake dogs. The clinical implication of these data is that esmolol administered to anesthetized patients may be expected to accentuate hemodynamic depression, but at effective doses (doses that block isoproterenol-induced increases in heart rate), hemodynamic stability is preserved.

Human Investigation

Published clinical studies have primarily dealt with 2 issues: the safety of esmolol in anesthetized patients and the efficacy of esmolol in blocking tachycardia and hypertension during the induction of anesthesia and tracheal intubation.[26–29] Three multicenter studies have investigated the safety and efficacy of esmolol in anesthetized patients undergoing carotid endarterectomy, coronary artery surgery and multiple, noncardiac surgical procedures (Table I); the results have not yet been published.

The hemodynamic effects of esmolol in anesthetized humans depend on several factors besides its

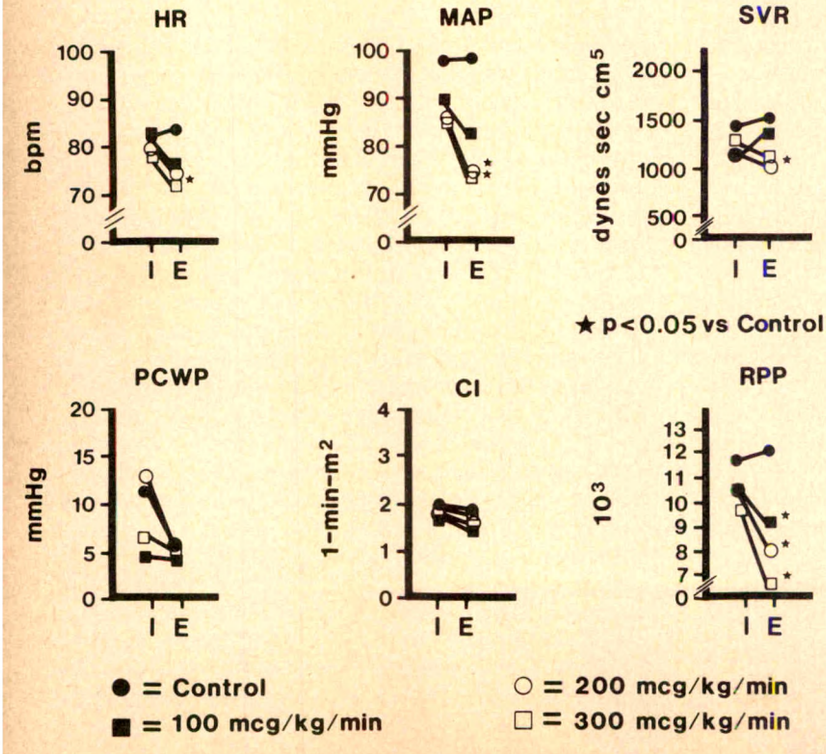

FIGURE 1. Hemodynamic effects of esmolol in patients anesthetized with diazepam, 0.5 mg/kg, N_2O:O_2 (50:50) and pancuronium, 0.1 mg/kg. Heart rate is significantly ($p < 0.05$) lower in esmolol-treated patients than in untreated control subjects. Esmolol 100 = infusion of 500 μg/kg/min 1 minute, then 100 μg/kg/min for 3 minutes; esmolol 200 = infusion of 500 μg/kg/min for 2 minutes, then 200 μg/kg/min for 2 minutes; and esmolol 300 = infusion of 500 μg/kg/min for 3 minutes, then 300 μg/kg/min for 1 minute. CI = cardiac index; E = esmolol infusion; HR = heart rate; I = induction of anesthesia; MAP = mean blood pressure; PCWP = pulmonary artery capillary wedge pressure; RPP = heart rate–systolic blood pressure product; SVR = systemic vascular resistance. Data from Menkhaus et al.[26]

intrinsic β-antagonist activity: concurrent anesthesia, underlying sympathetic tone, concurrent vasoactive drug therapy, intensity of the stressful stimulations and patient cardiovascular status. Understanding these interactions is essential if the effects of esmolol are to be compared in studies that differ with regard to anesthesia (e.g., ketamine vs thiopental), pharmacologic therapy (patients who did and those who did not receive β blockers), time of esmolol administration (before vs after intubation) and patient disease (normal cardiovascular system vs patients with coronary artery disease).

The hemodynamic effects of 3 infusion rates of esmolol (100, 200 and 300 μg/kg/min after loading with 500 μg/kg/min) were studied in patients undergoing coronary revascularization and the results were compared with those in a similar population of untreated control subjects[26] (Fig. 1). After induction of anesthesia with diazepam (0.5 mg/kg) and before intubation, esmolol infused at rates >100 μg/kg/min significantly ($p < 0.01$) decreased the heart rate (10% below the control group values) and systolic and mean blood pressures (20% below control group values). Cardiac index, systemic vascular resistence, pulmonary capillary wedge pressure and left ventricular stroke work index were not statistically different between the groups. Under these conditions, esmolol decreased the rate-pressure product significantly ($p < 0.001$) compared with control values and displayed a dose-related trend that was not statistically significant.

Esmolol protects patients from hypertension and tachycardia. In 1 study of patients with coronary artery disease, 1 minute after intubation, the heart rate was significantly ($p < 0.001$) lower in all esmolol-treated groups (15% below control group values).[26] The same was true for systolic and mean blood pressure (10 to 15% below control group values), whereas no differences were found within the esmolol groups. Cardiac index and the derived hemodynamic measurements were unchanged, but the rate-pressure product was significantly ($p < 0.001$) decreased (>20% below control group values) with a weak dose-related trend. The increases in heart rate and blood pressure were associated with increases in norepinephrine levels in the control patients but not in the esmolol-treated patients (Fig. 2). Fifteen minutes after termination of esmolol infusion, all hemodynamic values (directly measured and derived) returned to baseline levels, demonstrating the short-lived hemodynamic effect of esmolol.

Menkhaus et al[26] found that esmolol was well tolerated, with only 1 episode of hypotension (systolic blood pressure <90 mm Hg) and no episodes of impaired atrioventricular conduction. In 1 patient in each of the 4 groups, ST-segment changes compatible with ischemia developed. Their study emphasizes that esmolol can be safely used in association with diazepam–nitrous oxide anesthesia and that esmolol is effective in blocking the hemodynamic response to stressful stimuli by means of β-adrenergic receptor blockade, as suggested by the simultaneous increased norepinephrine plasma concentration during intubation. It confirms the short-lived activity of esmolol and its potentially beneficial effect on global myocardial oxygen balance as represented by the rate-pressure product, although the fact that ST-segment changes occurred reemphasizes the concept that regional ischemia can occur in the presence of an adequate global myocardial oxygenation. Menkhaus et al did not find a statistically significant dose-dependent effect, presumably because a sufficiently wide dosage regimen was not used or because steady state was not achieved at each infusion dosage.

Girard et al[27] reported that when esmolol was used according to a similar dosage protocol in patients undergoing coronary revascularization and anesthetized with high-dose fentanyl (75 μg/kg) in oxygen, the heart rate and cardiac index measured during a stress-free period (after intubation and before incision) decreased significantly ($p < 0.05$), but in a fashion similar

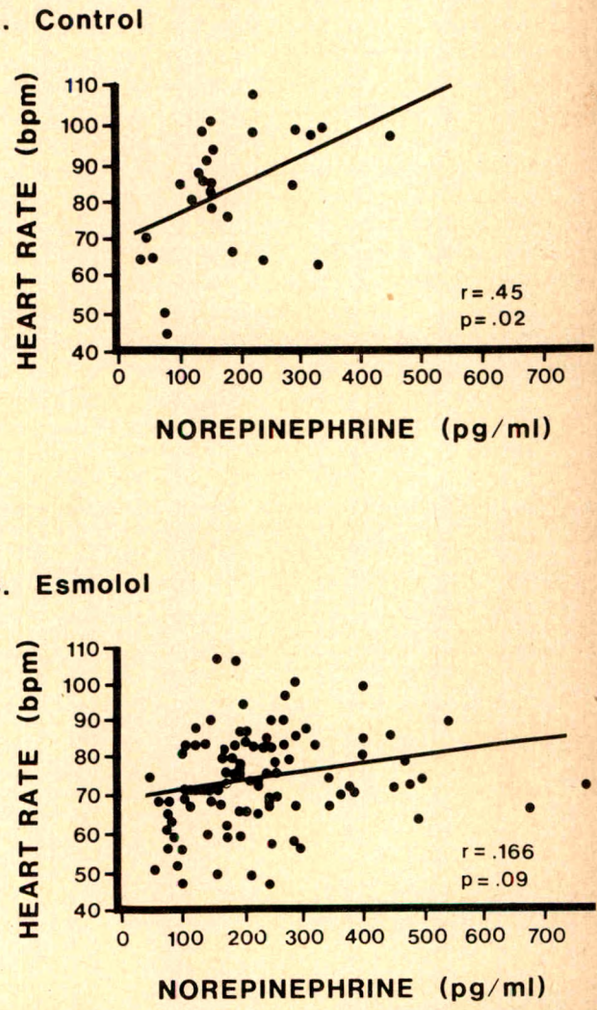

FIGURE 2. Heart rate (HR) and norepinephrine (NE) levels in patients with ischemic heart disease after endotracheal intubation. **A,** patients who did not receive esmolol; **B,** patients who received esmolol infusions of 100, 200 and 300 μg/kg/min. There is a weak but significant association between HR and NE in untreated patients, but a very poor association in the patients with β_1-adrenergic blockade with esmolol. This suggests β blockade of the adrenergic response to intubation.

to that in the control group. This study, while reconfirming the safety and short-lived action of esmolol (plasma level reached 8% of peak level 5 minutes after infusion and less than 2% of peak level after 30 minutes), emphasizes that concurrent factors, such as type and depth of anesthesia, intensity of stimulation and adrenergic response, affect the hemodynamic response.

Korenaga et al[28] investigated the effects of esmolol (500 μg/kg/min × 4 minutes followed by 300 μg/kg/min) during intubation in healthy patients given thiopental. The heart rate was lower (20% below control values) after intubation than in untreated control patients, as was systolic blood pressure (15% below control group values). In healthy patients anesthetized with ketamine,[29] esmolol (300 μg/kg/min × 10 minutes) was effective in decreasing heart rate and systolic blood pressure.

In summary, laboratory and clinical investigations indicate that esmolol is an effective β_1-adrenergic receptor antagonist that is well suited to attenuating the hemodynamic responses to stressful stimuli in the intraoperative period. Its pharmacokinetic characteristics (the rapid onset and elimination) make this agent particularly well suited for preventing and treating the adrenergic responses to intraoperative stresses, which can be very intense but often brief in duration.

Esmolol appears to be safe when used in combination with intravenous anesthetic agents; its marginal safety when used in combination with inhalation agents requires further investigation. Questions regarding the use of esmolol perioperatively in patients who are hypertensive, who have impaired ventricular function and who are receiving long-term β- and calcium-entry blocking therapies remain to be answered.

Discussion

Dr. Sonnenblick (Bronx, New York): One of the things that most of us are impressed about is that the perioperative myocardial infarction rates, which used to be immensely high, are now vastly lowered by having the patients go to surgery on their β blockers. Do you think it is reasonable to say that the surgical patient is safer on a β blocker if he has a potentially threatened ischemic myocardium?

Dr. Reves (Durham, North Carolina): I think that is true. I think we learned from the experience when propranolol was withdrawn before surgery. This procedure ended up precipitating some angina and infarction even before the operation. One of the worst things that happened to us as cardiac anesthetists was the introduction phase of calcium-channel blockers. When these drugs first appeared on the market, cardiologists took patients off their β blockers and surgical patients had fits with hypertension and tachycardia during surgery. Now, finally, surgical patients are back on β blockers. I don't know that the withholding of β blockers resulted in increased myocardial damage, but we certainly saw more ischemia. I think maintaining patients on their β blockers is useful, and to have a drug like esmolol, where one can give the patient a short-lasting β-blocker, is even more useful.

Dr. Lowenthal (Philadelphia, Pennsylvania): How much of a pressor response is there during intubation?

Dr. Reves: Well, it depends on the underlying anesthetic, ventricular function and a whole host of things. For example, in our patients, mean blood pressures rose to 130 mm Hg in the control group and were only about 110 in the esmolol group. However, that is because our patients were lightly anesthetized. If one looks at patients on high-dose opioids for intubation, you'll see that one can usually block a lot of that hypertension. You may see blood pressure increases to about a mean of around 90, and it's often transient.

Dr. Lowenthal: Do you think that the hypertension that Dr. Gray reported in coronary artery bypass graft patients might in part be related to prolonged intubation during and after surgery?

Dr. Reves: The answer to that is no. However, I know that there are responders and nonresponders and the patients who respond to intubation with high blood pressure levels are frequently those who will, when they begin to emerge from their anesthesia in the intensive care unit, have more problems with postoperative hypertension. We did a study looking at catecholamine levels several years ago, and we found that responders are those who really pour out a lot of norepinephrine. Clearly there is one group that does and one that does not respond to intubation with hypertension.

Dr. Morganroth (Philadelphia, Pennsylvania): How often did you see esmolol-induced hypotension, and in your personal experience, how do you treat it in a given setting?

Dr. Reves: The blood pressure went down, but not to very low levels. We had 1 patient who went to less than 90 mm Hg, so we turned off the esmolol and gave a little phenylephrine. In most of our experience, blood pressure hasn't really dropped too low. To treat it, I would discontinue the drug. Most perioperative hypotension is due to vasodilation caused by the induction of anesthesia, and we end up giving volume and phenylephrine.

Dr. Lee (McGaw Park, Illinois): I would like you to comment on the clinical significance of perioperative tachycardia and hypertension, and where you see esmolol fitting in—both in coronary artery bypass graft patients and in patients with coronary disease going for noncardiac surgery. Just where do you see esmolol being used?

Dr. Reves: I see that esmolol is going to be on the anesthesiologist's cart, and it is primarily going to be used in patients in whom you are really worried about increases in heart rate—that is, patients with ischemic heart disease. There are others, but for the most part that's the primary group. Esmolol will be used to tide the patient through sinus tachycardia or serious hypertension, and you will just either hang esmolol as a drip or you may even squirt it in. Because esmolol is so short-lived, you can get better and faster control of the situation—and then may deepen your anesthesia or whatever other manipulations you have to do. That is the beauty of esmolol, and I think it will be used a great deal by clinicians, particularly those accustomed to giving vasoactive drugs—principally anesthesiologists. I also think esmolol will be used quite frequently to control unwanted hypertension and tachycardia, particularly sinus tachycardia and problems during an operation. I don't think esmolol will be necessarily used to try to block the increase in heart rate for intubation in the healthy patient, because we know that that is well tolerated; we see it every day and it is not a serious problem. However, esmolol will be used in patients with ischemic heart disease undergoing cardiac and noncardiac surgery.

Dr. Lowenthal: Do you know whether there is any experience with the use of esmolol during pheochromocytoma surgery, and if so, is it better than propranolol?

Dr. Laddu (McGaw Park, Illinois): We do not have such experience in any of the patients we've studied; but we plan to study this area.

Dr. Lee: I would guess that such patients would be better controlled on esmolol.

Dr. Reves: Yes, that would obviously be a good place to use esmolol.

Dr. Gray (Los Angeles, California): I would like to add to Dr. Reves' earlier comments. As I see it, there are serious problems with using esmolol only in patients with supraventricular tachycardia. Hypotension may be a limitation and esmolol will have competition in the marketplace. Verapamil is pretty good for supraventricular tachycardia, as is propranolol and digoxin. But in the patient with hypertension—whether it is postoperative, a patient who walks in with a hypertensive crisis or the occasional postinfarction patient who has a hyperdynamic circulation—I think that's

a situation where you can almost be assured that you can give esmolol in very large doses and with great safety, based on everything I've seen today. Of course, there may be other factors that we haven't seen yet. The number of patients who may benefit from this drug is substantial. Just looking at the coronary bypass surgery market, if you will, the estimate in 1983 was that there were 190,000 coronary bypass surgeries performed. That's probably down a little in 1984, and maybe it will go further down in 1985. Let's say 150,000 patients have bypass surgery in 1985, of whom anywhere from 25 to 60% are hypertensive and, say, half of those would qualify for esmolol or some β blocker. I think we are looking at a sizable number of patients for which esmolol would be very good therapy.

Dr. Reves: I think it will be an adjunct to nitroprusside, too, in postoperative hypertension. At the moment, we think of drugs as appropriate for different patient groups, but I would be willing to bet that ultimately esmolol will be used right alongside nitroprusside in many of those postoperative hypotensive patients.

Dr. Morganroth: I could make the same comment about the verapamil issue, too. I would think one could argue that esmolol should be the first-line agent instead of verapamil, for the reasons we talked about before.

Dr. Reves: Yes, and verapamil causes profound hypotension. Every time I give verapamil, I'm just a little apprehensive because I know the blood pressure is going to go so low.

TWO-WAY LIPID REGULATOR

LOPID® *A Balanced Approach*

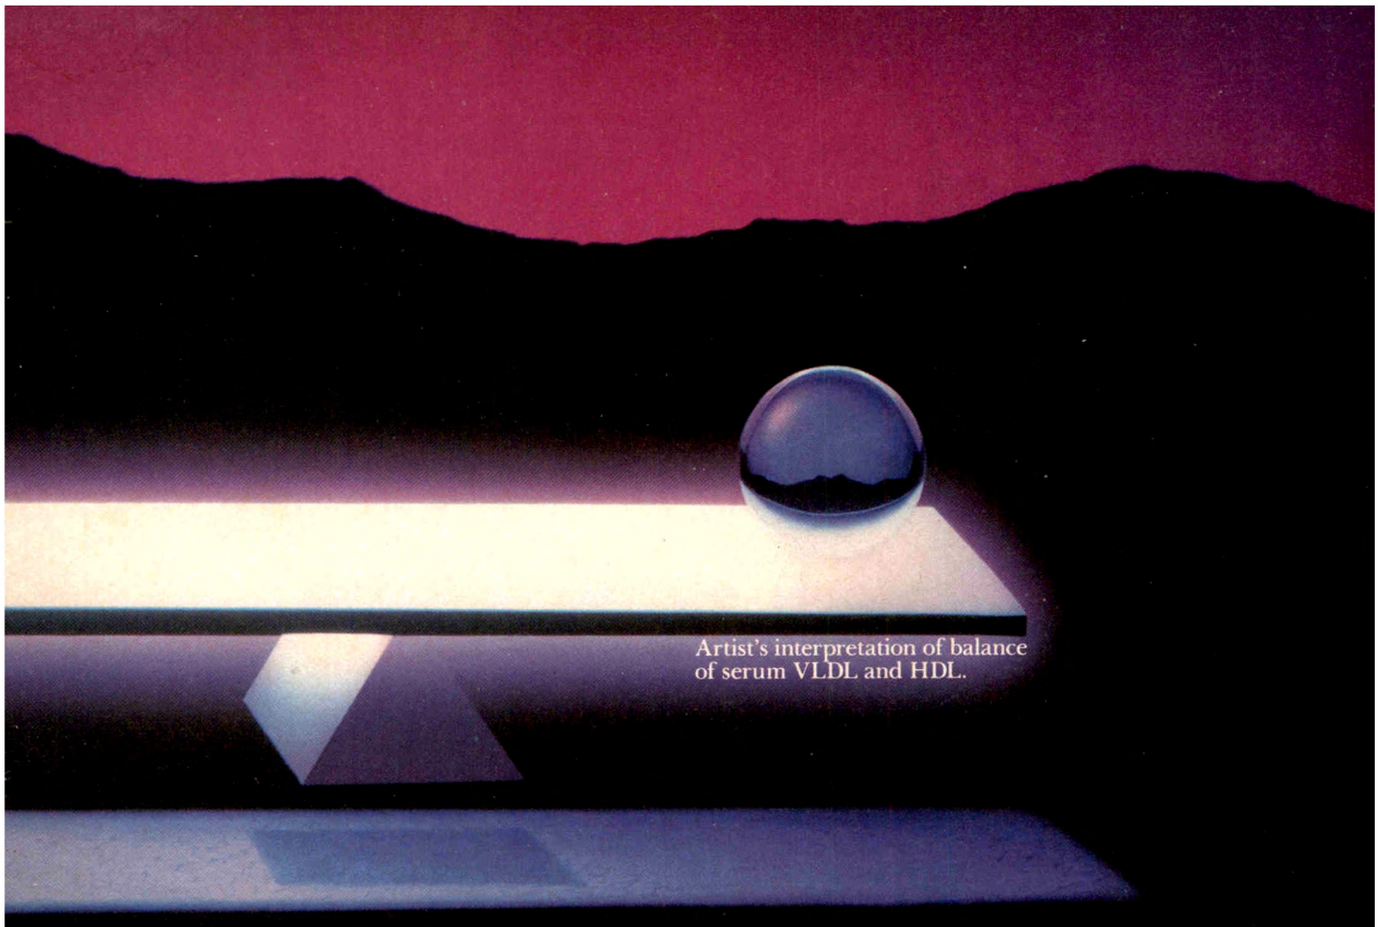
(gemfibrozil capsules, USP) 300 mg

Indicated for adult patients with high serum triglycerides (type IV hyperlipidemia) who present a risk of pancreatitis and who do not respond adequately to diet.

Clinical trials show that Lopid favorably regulates the balance of certain lipoproteins responsible for transport of serum lipids.

- Lowers elevated serum levels of triglyceride-rich very-low-density lipoproteins (VLDL) and, to a lesser extent, cholesterol-rich low-density lipoproteins (LDL)
- Favorably raises serum levels of high-density lipoproteins (HDL)
- Has a side effects profile similar to placebo and no significant abnormalities in clinical/laboratory evaluations
- Plus BID convenience

© 1984 Warner-Lambert Company

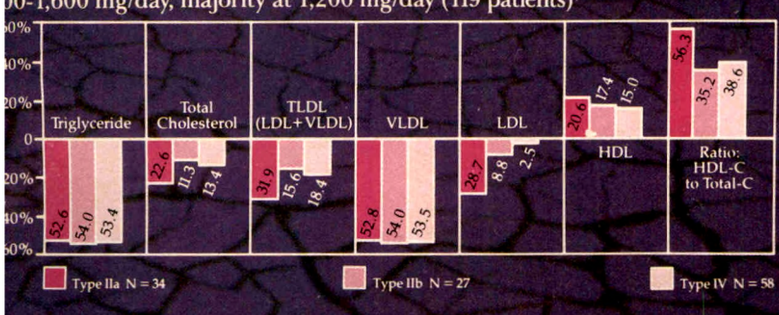


Artist's interpretation of balance of serum VLDL and HDL.

to Therapy of Certain Dyslipidemias

Lipid-regulating efficacy: open-label phase of US multicenter study at end of 12 lunar months*[1]

Average percent change from baseline at doses ranging from 800-1,600 mg/day, majority at 1,200 mg/day (119 patients)†



Diet, exercise and weight loss are the first choice in therapy of lipid disorders.

*Visit every 4 weeks during long-term use of LOPID.

†Data cited on this graph reflect clinical experience based on the multicenter trial. They do not imply an indication for Types IIa and IIb dyslipidemias.

PARKE-DAVIS

Please see following page for brief summary of prescribing information.

TWO-WAY LIPID REGULATOR

LOPID®

(gemfibrozil capsules, USP) 300 mg

Before prescribing, please see full prescribing information.
A Brief Summary follows.

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. In addition, LOPID may increase the high density lipoprotein (HDL) cholesterol fraction, an action considered of possible benefit to inhibition of the atherosclerotic process.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID also inhibits synthesis of VLDL carrier apoprotein, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following single doses and 1.3 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, primarily as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO
		Total	VLDL	LDL	HDL	HDL Cholesterol / Total Cholesterol
IIa	−44%	−4.2%	−44.3%	− 5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	− 6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk.

LOPID (gemfibrozil capsules, USP) has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. However, it must be understood that there is no evidence that use of any lipid-altering drug will be beneficial in preventing death from coronary heart disease (see WARNINGS). Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of drug-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings.)

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies: Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis—LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants—Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy**—Before instituting LOPID (gemfibrozil capsules, USP) therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy**—Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Seasonal Variation of Lipid Levels**—LOPID is not expected to alter seasonal variations of higher serum lipid values in mid-winter and late summer or the lower values in fall and spring.

4. **Impairment of Fertility**—Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

5. **Pregnancy Category B**—Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers**—Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes**—Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

8. **Liver Function**—Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

9. **Cardiac Arrhythmias**—Although no clinically significant abnormalities occurred that could be attributed to LOPID, the possibility exists that such abnormalities may occur.

10. **Use in Children**—Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria
Central Nervous System: headache, dizziness, blurred vision
Musculoskeletal: painful extremities
Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:
Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia
Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints
Central Nervous System: vertigo, insomnia, paresthesia, tinnitus
Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)
Miscellaneous: fatigue, malaise, syncope

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID (GEMFIBROZIL CAPSULES, USP). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

THE NEW MEDTRONIC® BIPOLAR SCREW-IN LEAD. SAFE PASSAGE, POSITIVE FIXATION, ASSURED.

Since the advent of the remarkably successful Medtronic 6957 and 6957J screw-in unipolar transvenous leads, physicians worldwide have asked for a bipolar version.

Now it's here. A dependable bipolar transvenous lead with a retractable, extendable electrode for safe venous passage and positive fixation. A concept proven in over 30,000 implants of the 6957 and 6957J leads since 1979.

Rigorously tested, the new model 4016 leads are outstanding performers. They provide the positive fixation only a screw-in lead can give. Use them safely in atrial or ventricular applications for low dislodgment rates with stable pacing and sensing performance.

The superiority of the patented "Bisping action" results from a helix that is retracted during passage of the lead so it is not exposed to venous tissue. After the lead is positioned, simply turn the connector pin and the helical electrode screws into the cardiac tissue. The helix is easily screwed out for repositioning or removal.

This superior method of lead fixation gets you and your patient out of the operating room or catheter lab faster. It dramatically reduces reoperations due to lead dislodgment.

Call 1-800-328-2518 (day or night) for more information. Or write: Physicians Information Service, Department T246, Medtronic, Inc., 7000 Central Avenue, Minneapolis, MN 55432.

Medtronic

Medtronic® Model 4016 Lead

Indications Medtronic Model 4016 Endocardial Screw-In Bipolar Leads are designed to be used in either the atrium or ventricle where a permanent single or dual chamber pacing system is indicated. **Contraindications** When tricuspid valvular disease is present, use of a ventricular endocardial lead is contraindicated. **Warnings** An implanted lead forms a direct, low-resistance current path to the myocardium. Care must be taken during surgical procedures to insulate connector pins from leakage currents that may arise from nearby line-powered equipment. **Precaution** To prevent damage to lead or potential lead dislodgment, do not use excessive force or surgical instruments in handling lead. Use an anchoring sleeve and avoid placing lead under extreme tension or angulation. **Potential Complications** Complications associated with pacemaker leads include cardiac perforation, dislodgment, fracture, infection, phrenic nerve stimulation, myocardial irritability and embolism.

The Original

...the only clinically-tested dipyridamole

Reliquary, for the heart of Anne of Brittany
Museum of Nantes

Crafted entirely in gold, the reliquary bears an eloquent inscription extolling the virtue of Anne, Duchess of Brittany and Queen of France. The reliquary dates from 1513.

dipyridamole Tablets of 25, 50 and 75 mg

Persantine®

The experienced dipyridamole

BRIEF SUMMARY

INDICATIONS—Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indication as follows:
"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency of, or eliminate, anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack. Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.
PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.
ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.
DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy. Tablets of 25, 50 and 75 mg. For complete details, please see the full prescribing information.

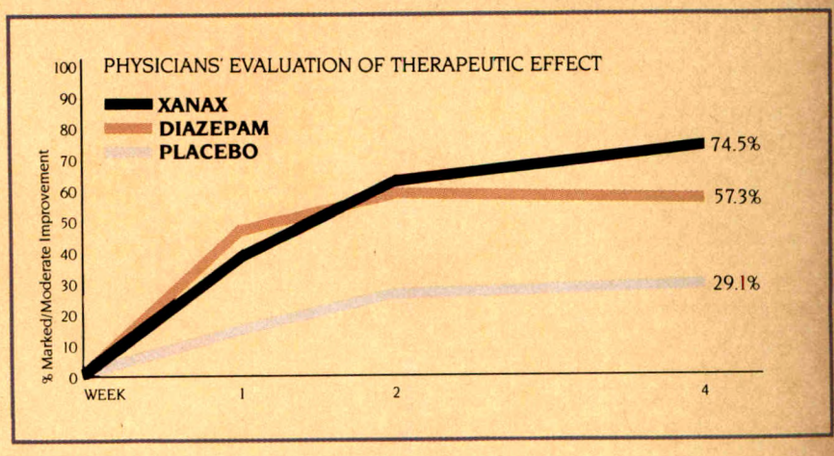
FOR CLINICAL ANXIETY

EFFICACY EQUAL TO DIAZEPAM WITH LESS DROWSINESS

In double-blind, placebo-controlled clinical trials in 976 patients with moderate to severe clinical anxiety, therapy with XANAX was compared to diazepam:*

Patients treated with XANAX *had a significantly lower incidence of drowsiness when compared directly to diazepam* therapy in *a 976-patient*, placebo-controlled, multicenter study:*

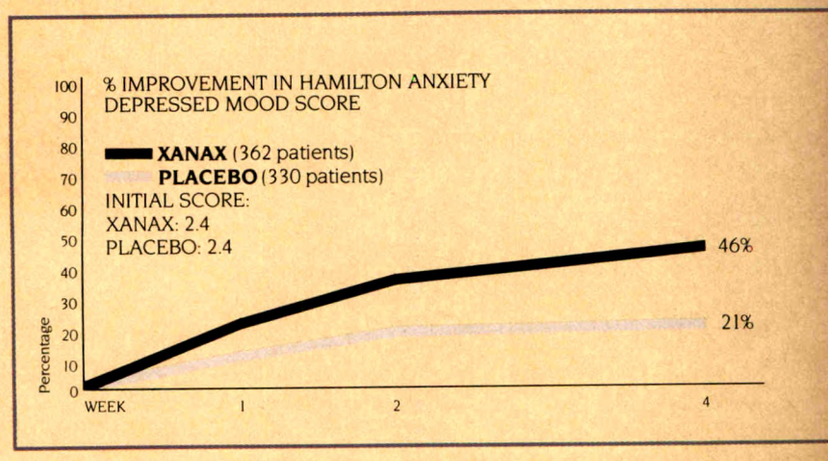


AND CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

EFFECTIVE IN CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

Patients with clinical anxiety may complain of having feelings of depression, such as sadness, blueness, or loneliness.

Depressed mood is one of 14 items on the Hamilton Anxiety Rating Scale. Special analysis of 692 anxious patients with a significant depressed mood item score showed that treatment with XANAX was significantly better than placebo in decreasing depressed mood score.



SIMPLE DOSAGE:
XANAX 0.25–0.5 mg T.I.D.

The usual starting dose of XANAX is 0.25 to 0.5 mg, three times daily.

Please see next page for brief summary of prescribing information.

Xanax® 0.5 mg Tablets

alprazolam Ⓒ

XANAX® Tablets
(alprazolam) ℞

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: The dosage of XANAX Tablets should be reduced or withdrawn gradually, since withdrawal seizures have been reported upon abrupt withdrawal. If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation. (See Drug Interaction section.) Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage. (See Dosage and Administration.) Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about: (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central nervous system: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting, and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other side effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analysis are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. Withdrawal seizures have occurred upon rapid decrease or abrupt discontinuation of therapy. In all patients, dosage should be gradually tapered under close supervision. Patients with a history of seizures or epilepsy should not be abruptly withdrawn from XANAX. Addiction-prone individuals should be under careful surveillance. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

DOSAGE AND ADMINISTRATION
The usual starting dose is 0.25 to 0.5 mg, t.i.d. Maximum total daily dose is 4 mg. In the elderly or debilitated, the usual starting dose is 0.25 mg, two or three times daily. Reduce dosage gradually when terminating therapy, by no more than one milligram every three days.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION.

CONTENTS IN BRIEF

CORONARY HEART DISEASE

705 **Effect of Intracoronary Thrombolytic Therapy on Exercise-Induced Ischemia After Acute Myocardial Infarction.** Jacques A. Melin, Patrick M. De Coster, Jean Renkin, Jean-Marie R. Detry, Christian Beckers, and Jacques Col

712 **Primary Angiographic Success Rates of Percutaneous Transluminal Coronary Angioplasty.** H. Vernon Anderson, Gary S. Roubin, Pierre P. Leimgruber, John S. Douglas, Jr., Spencer B. King III, and Andreas R. Gruentzig

718 **Digital Quantification Eliminates Intraobserver and Interobserver Variability in the Evaluation of Coronary Artery Stenosis.** Ran Vas, Neal Eigler, Calvin Miyazono, J. Martin Pfaff, Kenneth J. Resser, Mason Weiss, Thasana Nivatpumin, James Whiting, and James Forrester

724 **Comparison of Buccal Nitroglycerin and Oral Isosorbide Dinitrate for Nitrate Tolerance in Stable Angina Pectoris.** John O. Parker, Karen A. Vankoughnett, and Bernice Farrell

729 **Collateral Flow in Patients with Acute Myocardial Infarction.** William D. Nitzberg, Hrudaya P. Nath, William J. Rogers, William P. Hood, Jr., Patrick L. Whitlow, Russell Reeves, and William A. Baxley

737 **Frequency and Significance of Induced Sustained Ventricular Tachycardia or Fibrillation Two Weeks After Acute Myocardial Infarction.** Anil K. Bhandari, Jeffrey S. Rose, Adam Kotlewski, Shahbudin H. Rahimtoola, and Delon Wu

742 **Crossover from Intravenous to Transdermal Nitroglycerin Therapy in Unstable Angina Pectoris.** Shu-Guang Lin and John T. Flaherty

749 **Ischemia During Angioplasty After Streptokinase: A Marker of Myocardial Salvage.** Lowell F. Satler, Charles E. Rackley, Curtis E. Green, Randolph S. Pallas, David L. Pearle, Albert A. Del Negro, and Kenneth M. Kent

753 **Evaluation of Methods of Measurement and Estimation of Left Ventricular Function After Acute Myocardial Infarction.** Michael G. Jones, Barry W. Ramo, Gilbert L. Raff, Tomoaki Hinohara, and Galen S. Wagner

757 **Infections in a Coronary Care Unit.** Winston A. Schandorf, Richard B. Brown, Michael Sands, and David Hosmer

METHODS

761 **Determination of Left Ventricular Mass Using Single-Photon Emission Computed Tomography.** Christopher L. Wolfe, Donald E. Jansen, James R. Corbett, Kirk Lipscomb, Gregory Gabliani, Neil Filipchuk, Gregory Redish, Samuel E. Lewis, and James T. Willerson

764 **Analysis of Factors Affecting the Variability of Fick Versus Indicator Dilution Measurements of Cardiac Output.** L. David Hillis, Brian G. Firth, and Michael D. Winniford

769 **Effect of Damped Sine-Wave Shocks on Catheter Dielectric Strength.** Gust H. Bardy, Fernando Coltorti, Tom D. Ivey, Dan Yerkovich, and H. Leon Greene

773 **Value of Intraoperative Left Ventricular Microbubbles Detected by Transesophageal Two-Dimensional Echocardiography in Predicting Neurologic Outcome After Cardiac Operations.** Eric J. Topol, Linda S. Humphrey, A. Michael Borkon, William A. Baumgartner, Debra L. Dorsey, Bruce A. Reitz, and James L. Weiss

776 **Right Ventricular Ejection Fraction Measured by First-Pass Intravenous Krypton-81m: Reproducibility and Comparison with Technetium-99m.** Dean F. Wong, T.K. Natarajan, Warren Summer, Paul A. Tibbits, Thomas Beck, Daniel Koller, Wayne Kasecamp, James Lamb, Joseph Olynyk, Mary Sue Philp, Marshall Bryan, and Henry N. Wagner, Jr.

781 **Measurement of Left Ventricular Volume Using Single-Photon Emission Computed Tomography.** Gary S. Caputo, Michael M. Graham, Kirk D. Brust, J. Ward Kennedy, and Wil B. Nelp

BRIEF REPORTS

787 **Echocardiographic Detection of Complete and Partial Papillary Muscle Rupture During Acute Myocardial Infarction.** Patricia C. Come, Marilyn F. Riley, Ronald Weintraub, James P. Morgan, and Shoichiro Nakao

789 **Sequential Balloon Technique in Angioplasty of Severe Coronary Arterial Obstructions.** David C. Levin, Lawrence M. Boxt, Richard Abben, J. Daniel Garnic, James M. Kirshenbaum, Dale Adler, Thomas Shook, Peter Friedman, and Peter Ganz

792 **Surgical Treatment of Medically Refractory Variant Angina Pectoris: Segmental Coronary Resection with Aortocoronary Bypass and Plexectomy.** Christopher DiPaolo, Nicholas Z. Kerin, Melvyn Rubenfire, and Frederick Levine

794 **Relation of Acute Myocardial Infarction to Cocaine Abuse.** Louis L. Cregler and Herbert Mark

794 **Coronary Arterial Findings After Accidental Death Immediately After Successful Percutaneous Transluminal Coronary Angioplasty.** Alan L. Soward, Catherina E. Essed, and Patrick W. Serruys

796 **Exercise-Related Bundle Branch Block in Children.** J. Timothy Bricker, Malinda S. Traweek, David A. Danford, Thomas A. Vargo, and Arthur Garson, Jr.

797 **Pacemaker Twiddler's Syndrome: An Important Cause o Diaphragmatic Pacing.** Anil Kumar, Charles R. McKay, an Shahbudin H. Rahimtoola

799 **Arrhythmogenic Right Ventricular Dysplasia in a Family** Michael A. Ruder, Stuart A. Winston, Jesse C. Davis, Josep A. Abbott, Michael Eldar, and Melvin M. Scheinman

800 **Induction and Termination of Ventricular Tachycardia b Changing Body Posture.** Tohru Ohe, Yosiaki Tomobuchi, an Katsuro Shimomura

802 **Norepinephrine Infusions in Congestive Heart Failure.** Steve R. Goldsmith, Gary S. Francis, and Jay N. Cohn

804 **Upright Paradoxical Posterior Wall Movement in Mitral Valv Prolapse.** Jack Krafchek, Mary Shaw, and Joseph Kisslo

806 **Safety of Labor and Delivery in Women with Mitral Valve Prolapse.** Edward P. Shapiro, Edward L. Trimble, J. Courtland Robinson, Myrna T. Estruch, and Sheldon H. Gottlieb

808 **Mitral Valve Prolapse and Addictions.** Jon Christopher Stringer, Anis Obeid, and Eleanor O'Shea

809 **Significance of E Point-Septal Separation by M-Mode Echocardiography in Patients with Aortic Regurgitation.** Maxine H. Rosoff and Michael V. Cohen

811 **Auscultation, M-Mode Echocardiography and Pulsed Doppler Echocardiography Compared with Angiography for Diagnosis of Chronic Aortic Regurgitation.** David G. Meyers, Terry S. Olson, and Dale A. Hansen

812 **Left Atrial Mobile Thrombus in Hypertrophic Cardiomyopathy.** Mareomi Hamada, Wataru Matsubara, Naoaki Tomita, Yusuke Miyauchi, and Tatsuo Kokubu

814 **Acute Left Ventricular Dysfunction and Thrombosis Following Natural Gas Poisoning.** Raymond P. Kelly and Dwain A. Owensby

815 **Massive Endocardial Calcification Associated with Endomyocardial Fibrosis.** Mária Lengyel, Attila Árvay, and Imre Palik

816 **Effect of Intense Aerobic Training on Exercise Performance in Children After Surgical Repair of Tetralogy of Fallot or Complete Transposition of the Great Arteries.** Linda M. Bradley, Frank M. Galioto, Jr., Paul Vaccaro, Denise A. Hansen, and Jane Vaccaro

818 **Coarctation of the Aorta Inherited as an Autosomal Dominant Trait.** Robert H. Beekman and Meinhard Robinow

821 **Two-Dimensional Echocardiographic Diagnosis of Total Anomalous Pulmonary Venous Connection Below the Diaphragm.** Pui-Kan Liao, Wen-Jen Su, and Jui-Sung Hung

822 **Computerized Tomography and Ultrasound in the Noninvasive Evaluation of Coarctation of the Aorta.** Maria Grazia Modena, Alberto Benassi, Giorgio Mattioli, Novella Guicciardi, Renato Romagnoli, and Giancarlo Canossi

INSTRUCTIONS TO AUTHORS on page 820

FOR HEART FAILURE
Available in 12.5 mg Tablets

GIVE THE GIFT OF MORE ACTIVE LIVING

CAPOTEN enhances patients' quality of life

☐ CAPOTEN relieves major heart failure symptoms, improves functional capacity.[1]

☐ Use CAPOTEN when symptoms persist despite digitalis and diuretic therapy.

ACE*INHIBITOR

CAPOTEN® (captopril tablets) IN HEART FAILURE†

YOUR FIRST CHOICE AFTER DIGITALIS AND DIURETICS

*Angiotensin Converting Enzyme

†CAPOTEN is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis. In using CAPOTEN, consideration should be given to the risk of neutropenia/agranulocytosis. Use special precautions in patients with impaired renal function, collagen vascular disorders, or those exposed to other drugs (e.g., procainamide) known to affect the white cells or immune response. Evaluation of heart failure patients should always include assessment of renal function. See INDICATIONS, WARNINGS, and ADVERSE REACTIONS in the brief summary on the adjacent page.

CAPOTEN® TABLETS
Captopril Tablets

INDICATIONS: Hypertension – CAPOTEN (captopril) is indicated for the treatment of hypertension. Consideration should be given to the risk of neutropenia/agranulocytosis (see WARNINGS). CAPOTEN may be used as initial therapy for patients with normal renal function, in whom the risk is relatively low. In patients with impaired renal function, particularly those with collagen vascular disease, captopril should be reserved for those who have either developed unacceptable side effects on other drugs, or have failed to respond satisfactorily to drug combinations. CAPOTEN is effective alone and in combination with other antihypertensive agents, especially thiazide-type diuretics.

Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

WARNINGS: Neutropenia/Agranulocytosis – Neutropenia (<1000/mm³) with myeloid hypoplasia has resulted from use of captopril. About half of the neutropenic patients developed systemic or oral cavity infections or other features of the syndrome of agranulocytosis. The risk of neutropenia is dependent on the clinical status of the patient:

In clinical trials in patients with hypertension who have normal renal function (serum creatinine <1.6 mg/dL and no collagen disease), neutropenia has been seen in one patient out of over 8,600 exposed. In patients with some degree of renal failure (serum creatinine at least 1.6 mg/dL) but no collagen vascular disease, the risk in clinical trials was about 1 per 500. Doses were relatively high in these patients, particularly in view of their diminished renal function. In patients with collagen vascular diseases (e.g., systemic lupus erythematosus, scleroderma) and impaired renal function, neutropenia occurred in 3.7% of patients in clinical trials. While none of the over 750 patients in formal clinical trials of heart failure developed neutropenia, it has occurred during subsequent clinical experience. Of reported cases, about half had serum creatinine ≥ 1.6 mg/dL and more than 75% received procainamide. In heart failure, it appears that the same risk factors for neutropenia are present.

Neutropenia has appeared within 3 months after starting therapy, associated with myeloid hypoplasia and frequently accompanied by erythroid hypoplasia and decreased numbers of megakaryocytes (e.g., hypoplastic bone marrow and pancytopenia); anemia and thrombocytopenia were sometimes seen. Neutrophils generally returned to normal in about 2 weeks after captopril was discontinued, and serious infections were limited to clinically complex patients. About 13% of the cases of neutropenia have ended fatally, but almost all fatalities were in patients with serious illness, having collagen vascular disease, renal failure, heart failure or immunosuppressant therapy, or a combination of these complicating factors.

Evaluation of the hypertensive or heart failure patient should always include assessment of renal function. If captopril is used in patients with impaired renal function, white blood cell and differential counts should be evaluated prior to starting treatment and at approximately 2-week intervals for about 3 months, then periodically. In patients with collagen vascular disease or who are exposed to other drugs known to affect the white cells or immune response, particularly when there is impaired renal function, captopril should be used only after an assessment of benefit and risk, and then with caution. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat, fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.

Proteinuria – Total urinary proteins >1 g/day were seen in about 0.7% of patients on captopril. About 90% of affected patients had evidence of prior renal disease or received high doses (>150 mg/day), or both. The nephrotic syndrome occurred in about one-fifth of proteinuric patients. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients. Since most cases of proteinuria occurred by the 8th month of therapy, patients with prior renal disease or those receiving captopril at doses >150 mg/day should have urinary protein estimates (dip-stick on 1st morning urine) before therapy, and periodically thereafter.

Hypotension – Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]).

In heart failure, where blood pressure was either normal or low, transient decreases in mean blood pressure >20% were recorded in about half of the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

PRECAUTIONS: General: *Impaired Renal Function,* Hypertension – Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure – About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* – A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis due to decreased afterload reduction.

Surgery/Anesthesia – If hypotension occurs during major surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.

Drug Interactions: *Hypotension: Patients on Diuretic Therapy* – Precipitous reduction of blood pressure may occasionally occur within the 1st hour after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretics, and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy or by initiating therapy with small doses (6.25 or 12.5 mg). Alternatively, provide medical supervision for at least 1 hour after the initial dose.

Agents Having Vasodilator Activity – In heart failure patients, vasodilators should be administered with caution.

Agents Causing Renin Release – Captopril's effect will be augmented by antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity – The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium – Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium. Use potassium-containing salt substitutes with caution.

Inhibitors of Endogenous Prostaglandin Synthesis – Indomethacin and other nonsteroidal anti-inflammatory agents may reduce the antihypertensive effect of captopril, especially in low renin hypertension.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Pregnancy: Category C – There are no adequate and well-controlled studies in pregnant women. Embryocidal effects were observed in rabbits. Therefore, captopril should be used during pregnancy only if the potential benefit outweighs the potential risk to the fetus. Captopril crosses the human placenta.

Nursing Mothers: Captopril is secreted in human milk. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age. Dosage, on a weight basis, was comparable to that used in adults. Captopril should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving approximately 7000 patients.

Renal – About 1 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

Hematologic – Neutropenia/agranulocytosis have occurred (see WARNINGS). Anemia, thrombocytopenia, and pancytopenia have been reported.

Dermatologic – Rash (usually maculopapular, rarely urticarial), often with pruritus and sometimes with fever and eosinophilia, in about 4 to 7 of 100 patients (depending on renal status and dose), usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 1000 patients – reversible on discontinuance of captopril therapy. One case of laryngeal edema reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular – Hypotension may occur, see WARNINGS and PRECAUTIONS (Drug Interactions) for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia – About 2 to 4 (depending on renal status and dose) of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, cough, alopecia, and paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although no causal relationship has been established. Rarely cholestatic jaundice and hepatocellular injury with or without secondary cholestasis, have been reported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertensive patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern is correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be taken one hour before meals. In hypertension, CAPOTEN may be dosed bid or tid. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of 12.5, 25, 50, and 100 mg in bottles of 100 (25 mg also available in bottles of 1000), and in UNIMATIC® single dose packs of 100 tablets.

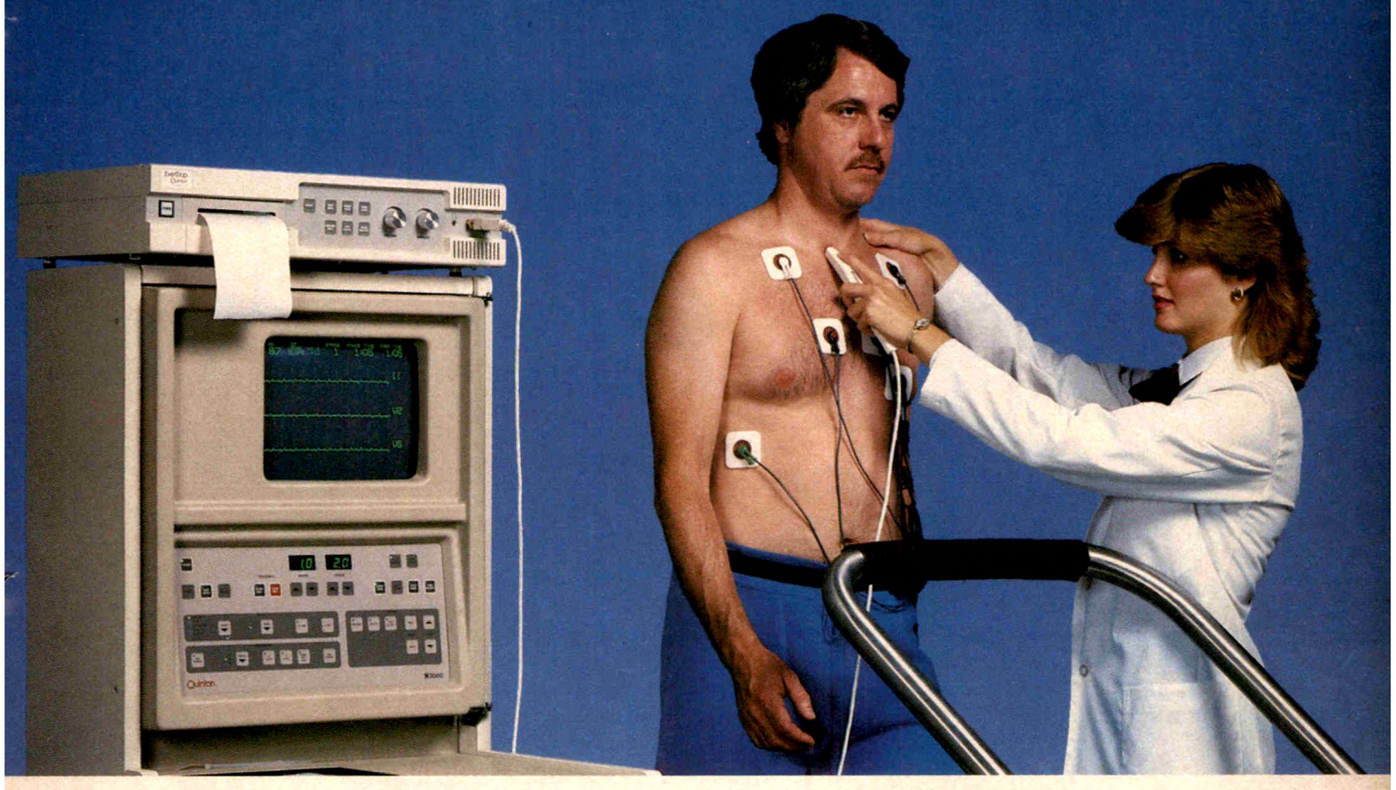
INNOVATORS IN CARDIOVASCULAR MEDICINE

© 1985 E. R. Squibb & Sons, Inc., Princeton, NJ 08540 525-518 Issued: September 1985

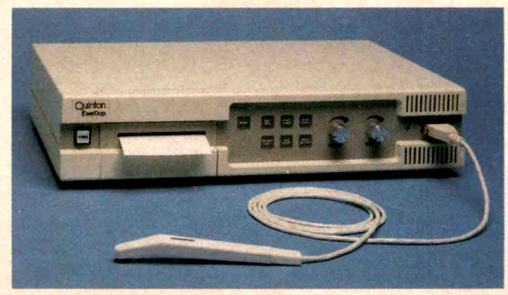
Introducing a Noninvasive Method for Assessing Left Ventricular Function



ıinton Instrument Company proud to announce *erDop*. . . the new diagnostic ol that makes ventricular ıction assessment inexpensive, e of radiation risks, and hnically simple—all advantages er radioisotope methods.

ıe velocity and acceleration of ood ejected from the left ıtricle are reliable indicators of ıtricular function. In fact, a owing body of evidence points peak acceleration as its most ısitive indicator. **ExerDop** is the ly continuous wave Doppler trument capable of recording *tantaneous peak velocity, peak eleration, and stroke distance* on a at-to-beat basis. Data is printed t immediately after each heart-at and the tabular final report mmarizes data sets and rcentage changes.

Many cardiologists evaluate the deterioration of a patient's ventricular function under stress prior to making surgical decisions regarding the need for coronary bypass. **ExerDop** can be used to record pertinent data while the patient is either exercising or is at rest. It is a stand-alone system that can be used in conjunction with any stress measurement system. And, because it's noninvasive, **ExerDop** is extremely useful for serial studies of left ventricular performance.



Now accurate peak velocity and acceleration data can be obtained quickly, easily, and inexpensively—making **ExerDop** a valuable tool for cardiologists, laboratory researchers, and clinical diagnosticians. For more information, please contact:

CORONARY HEART DISEASE

705 Effect of Intracoronary Thrombolytic Therapy on Exercise-Induced Ischemia After Acute Myocardial Infarction

JACQUES A. MELIN, PATRICK M. De COSTER, JEAN RENKIN, JEAN-MARIE R. DETRY, CHRISTIAN BECKERS, and JACQUES COL

Thirty-nine patients enrolled in an angiographically randomized trial of intracoronary streptokinase (SK patients treated with SK; 20 control subjects) underwent thallium-201 scintigraphy at rest and during stress 5 weeks after acute myocardial infarction. The patients were classified into 2 groups based on the presence 13) or absence (n = 26) of complete obstruction of the infarct-related coronary artery at the end of the acut giographic procedure. Semiquantitative score of myocardial thallium uptake was expressed as perce maximal defect score. Thallium defect score at rest between admission and 5 to 6 weeks' study decreased 10 ± 16% units in the control group and from 23 ± 14% units in the SK group (p = 0.01). This decrease wa lated to opening of the infarct-related artery (opening 23 ± 16% vs occlusion 5 ± 10%). The change in the cise-induced defect score was significantly (p = 0.01) larger in patients in the SK group (11 ± 6% units) th those in the control group (5 ± 7% units). The exercise perfusion defect was larger (p = 0.006) in patients incomplete obstruction or reperfusion (10 ± 6% units) than in patients with complete obstruction (3 ± 7% u This difference was independent of the number of diseased coronary vessels. Thus, in this group of patients were studied 5 to 6 weeks after acute myocardial infarction, patients treated with SK showed scintigra improvement at rest compared with results on admission, but had more exercise-induced ischemia; this related to incomplete coronary obstruction or reperfusion.

712 Primary Angiographic Success Rates of Percutaneous Transluminal Coronary Angioplasty

H. VERNON ANDERSON, GARY S. ROUBIN, PIERRE P. LEIMGRUBER, JOHN S. DOUGLAS, Jr., SPENCER B. KING III, and ANDREAS R. GRUENTZIG

Since the advent of coronary angioplasty, 3 distinct periods in catheter design can be identified. Double-lu balloon catheters with a fixed, flexible guidewire were first used. These were replaced with indepen steerable guidewires and catheters. Finally, the low-profile catheter was introduced. We separated our ex ence in 2,969 patients undergoing single-vessel percutaneous transluminal coronary angioplasty of a n coronary artery into 3 periods corresponding to the use of the 3 distinct catheter types. Before introducti steerable and low-profile catheters there was a significant difference among the 3 major coronary arteries i ability to reach and cross stenoses. This difference no longer exists. The percentage of total percutan transluminal coronary angioplasty attempts in the left anterior descending artery has decreased, whereas i left circumflex and right coronary arteries it has increased. Stenoses in all 3 major coronary arteries are equally accessible and primary success rates are similar.

718 Digital Quantification Eliminates Intraobserver and Interobserver Variability in the Evaluation of Coronary Artery Stenosis

RAN VAS, NEAL EIGLER, CALVIN MIYAZONO, J. MARTIN PFAFF, KENNETH J. RESSER, MASON WEISS, THASANA NIVATPUMIN, JAMES WHITING, and JAMES FORRESTER

Four experienced angiographers independently determined percent diameter narrowing of 36 stenoses us methods: by subjective analysis of single-frame cine film images (film); by subjective analysis of digital nonenhanced single-frame images (digital); and by using a semiautomated digital caliper quantitation sy

NORMODYNE®

Tablets (labetalol HCl)

NORMODYNE®

brand of labetalol hydrochloride

Tablets

BRIEF SUMMARY

INDICATIONS AND USAGE

NORMODYNE (labetalol HCl) Tablets are indicated in the management of hypertension. NORMODYNE Tablets may be used alone or in combination with other antihypertensive agents, especially thiazide and loop diuretics.

CONTRAINDICATIONS

NORMODYNE (labetalol HCl) Tablets are contraindicated in bronchial asthma, overt cardiac failure, greater than first degree heart block, cardiogenic shock, and severe bradycardia (see **WARNINGS**).

WARNINGS

Cardiac Failure Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure. Beta blockade carries a potential hazard of further depressing myocardial contractility and precipitating more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, labetalol HCl can be used with caution in patients with a history of heart failure who are well-compensated. Congestive heart failure has been observed in patients receiving labetalol HCl. Labetalol HCl does not abolish the inotropic action of digitalis on heart muscle.

In Patients Without a History of Cardiac Failure In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, NORMODYNE (labetalol HCl) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal Angina pectoris has not been reported upon labetalol HCl discontinuation. However, hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered NORMODYNE (labetalol HCl), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, NORMODYNE (labetalol HCl) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue NORMODYNE (labetalol HCl) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis and emphysema) Patients with bronchospastic disease should, in general, not receive beta-blockers. NORMODYNE may be used with caution, however, in patients who do not respond to, or cannot tolerate, other antihypertensive agents. It is prudent, if NORMODYNE is used, to use the smallest effective dose, so that inhibition of endogenous or exogenous beta-agonists is minimized.

Pheochromocytoma Labetalol HCl has been shown to be effective in lowering the blood pressure and relieving symptoms in patients with pheochromocytoma. However, paradoxical hypertensive responses have been reported in a few patients with this tumor; therefore, use caution when administering labetalol HCl to patients with pheochromocytoma.

Diabetes Mellitus and Hypoglycemia Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; it may therefore be necessary to adjust the dose of antidiabetic drugs.

Major Surgery The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial. Protracted severe hypotension and difficulty in restarting or maintaining a heart beat have been reported with beta-blockers. The effect of labetalol HCl's alpha-adrenergic activity has not been evaluated in this setting.

A synergism between labetalol HCl and halothane anesthesia has been shown (see **Drug Interactions**).

PRECAUTIONS

General *Impaired Hepatic Function* NORMODYNE (labetalol HCl) Tablets should be used with caution in patients with impaired hepatic function since metabolism of the drug may be diminished.

Jaundice or Hepatic Dysfunction On rare occasions, labetalol HCl has been associated with jaundice (both hepatic and cholestatic). It is therefore recommended that treatment with labetalol HCl be stopped immediately should a patient develop jaundice or laboratory evidence of liver injury. Both have been shown to be reversible on stopping therapy.

Information for Patients

As with all drugs with beta-blocking activity, certain advice to patients being treated with labetalol HCl is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. While no incident of the abrupt withdrawal phenomenon (exacerbation of angina pectoris) has been reported with labetalol HCl, dosing with NORMODYNE Tablets should not be interrupted or discontinued without a physician's advice. Patients being treated with NORMODYNE Tablets should consult a physician at any sign of impending cardiac failure. Also, transient scalp tingling may occur, usually when treatment with NORMODYNE Tablets is initiated (see **ADVERSE REACTIONS**).

Laboratory Tests

As with any new drug given over prolonged periods, laboratory parameters should be observed over regular intervals. In patients with concomitant illnesses, such as impaired renal function, appropriate tests should be done to monitor these conditions.

Drug Interactions

In one survey, 2.3% of patients taking labetalol HCl in combination with tricyclic antidepressants experienced tremor as compared to 0.7% reported to occur with labetalol HCl alone. The contribution of each of the treatments to this adverse reaction is unknown but the possibility of a drug interaction cannot be excluded.

Drugs possessing beta-blocking properties can blunt the bronchodilator effect of beta-receptor agonist drugs in patients with bronchospasm; therefore, doses greater than the normal anti-asthmatic dose of beta-agonist bronchodilator drugs may be required.

Cimetidine has been shown to increase the bioavailability of labetalol HCl. Since this could be explained either by enhanced absorption or by an alteration of hepatic metabolism of labetalol HCl, special care should be used in establishing the dose required for blood pressure control in such patients.

Synergism has been shown between halothane anesthesia and intravenously administered labetalol HCl. During controlled hypotensive anesthesia using labetalol HCl in association with halothane, high concentrations (3% or above) of halothane should not be used because the degree of hypotension will be increased and because of the possibility of a large reduction in cardiac output and an increase in central venous pressure. The anesthesiologist should be informed when a patient is receiving labetalol HCl.

Labetalol HCl blunts the reflex tachycardia produced by nitroglycerin without preventing its hypotensive effect. If labetalol HCl is used with nitroglycerin in patients with angina pectoris, additional antihypertensive effects may occur.

Drug/Laboratory Test Interactions

The presence of a metabolite of labetalol in the urine may result in falsely increased levels of urinary catecholamines when measured by a nonspecific trihydroxyindole (THI) reaction. In screening patients suspected of having a pheochromocytoma and being treated with labetalol HCl, specific radioenzymatic or high performance liquid chromatography assay techniques should be used to determine levels of catecholamines or their metabolites.

Carcinogenesis, Mutagenesis, Impairment of Fertility

Long-term oral dosing studies with labetalol HCl for 18 months in mice and for 2 years in rats showed no evidence of carcinogenesis. Studies with labetalol HCl, using dominant lethal assays in rats and mice, and exposing microorganisms according to modified Ames tests, showed no evidence of mutagenesis.

Pregnancy Category C

Teratogenic studies have been performed with labetalol in rats and rabbits at oral doses up to approximately 6 and 4 times the maximum recommended human dose (MRHD), respectively. No reproducible evidence of fetal malformations was observed. Increased fetal resorptions were seen in both species at doses approximating the MRHD. There are no adequate and well-controlled studies in pregnant women. Labetalol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects

Infants of mothers who were treated with labetalol HCl for hypertension during pregnancy did not appear to be adversely affected by the drug. Oral administration of labetalol to rats during late gestation through weaning at doses of 2 to 4 times the MRHD caused a decrease in neonatal survival.

Labor and Delivery

Labetalol HCl given to pregnant women with hypertension did not appear to affect the usual course of labor and delivery.

Nursing Mothers

Small amounts of labetalol (approximately 0.004% of the maternal dose) are excreted in human milk. Caution should be exercised when NORMODYNE Tablets are administered to a nursing woman.

Pediatric Use

Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Most adverse effects are mild, transient and occur early in the course of treatment. In controlled clinical trials of 3 to 4 months duration, discontinuation of NORMODYNE (labetalol HCl) Tablets due to one or more adverse effects was required in 7% of all patients. In these same trials, beta-blocker control agents led to discontinuation in 8 to 10% of patients, and a centrally acting alpha-agonist in 30% of patients.

The incidence rates of adverse reactions listed in the following table were derived from multicenter controlled clinical trials, comparing labetalol HCl, placebo, metoprolol and propranolol, over treatment periods of 3 and 4 months. Where the frequency of adverse effects for labetalol HCl and placebo is similar, causal relationship is uncertain. The rates are based on adverse reactions considered probably drug-related by the investigator. If all reports are considered, the rates are somewhat higher (e.g., dizziness 20%, nausea 14%, fatigue 11%), but the overall conclusions are unchanged.

	Labetalol HCl (N = 227) %	Placebo (N = 98) %	Propranolol (N = 84) %	Metoprolol (N = 49) %
Body as a whole				
fatigue	5	0	12	12
asthenia	1	1	1	0
headache	2	1	1	2
Gastrointestinal				
nausea	6	1	1	2
vomiting	<1	0	0	0
dyspepsia	3	1	1	0
abdominal pain	0	0	1	2
diarrhea	<1	0	2	0
taste distortion	1	0	0	0
Central and Peripheral Nervous Systems				
dizziness	11	3	4	4
paresthesias	<1	0	0	0
drowsiness	<1	2	2	2
Autonomic Nervous System				
nasal stuffiness	3	0	0	0
ejaculation failure	2	0	0	0
impotence	1	0	1	3
increased sweating	<1	0	0	0
Cardiovascular				
edema	1	0	0	0
postural hypotension	1	0	0	0
bradycardia	0	0	5	12
Respiratory				
dyspnea	2	0	1	2
Skin				
rash	1	0	0	0
Special Senses				
vision abnormality	1	0	0	0
vertigo	2	1	0	0

The adverse effects were reported spontaneously and are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, i.e., a group excluding patients with bronchospastic disease, overt congestive heart failure, or other contraindications to beta-blocker therapy.

Clinical trials also included studies utilizing daily doses up to 2400 mg in more severely hypertensive patients. Certain of the side effects increased with increasing dose as shown in the table below which depicts the entire U.S. therapeutic trials data base for adverse reactions that are clearly or possibly dose related.

Labetalol HCl Daily Dose (mg)	200	300	400	600
Number of Patients	522	181	606	608
Dizziness (%)	2	3	3	3
Fatigue	2	1	4	4
Nausea	<1	0	1	2
Vomiting	0	0	<1	<1
Dyspepsia	1	0	2	1
Paresthesias	2	0	2	2
Nasal Stuffiness	1	1	2	2
Ejaculation Failure	0	2	1	2
Impotence	1	1	1	1
Edema	1	0	1	1

Labetalol HCl Daily Dose (mg)	800	900	1200	1600	2400
Number of Patients	503	117	411	242	175
Dizziness (%)	5	1	9	13	16
Fatigue	5	3	7	6	10
Nausea	4	0	7	11	19
Vomiting	<1	0	1	2	3
Dyspepsia	1	0	2	2	4
Paresthesias	1	1	2	5	5
Nasal Stuffiness	2	2	4	5	6
Ejaculation Failure	3	0	4	3	5
Impotence	2	4	3	4	3
Edema	1	0	1	2	2

In addition, a number of other less common adverse events have been reported in clinical trials or the literature:

Cardiovascular Postural hypotension, including rarely, syncope.

Central and Peripheral Nervous Systems Paresthesias, most frequently described as scalp tingling. In most cases, it was mild, transient and usually occurred at the beginning of treatment.

Collagen Disorders Systemic lupus erythematosus; positive antinuclear factor (ANF).

Eyes Dry eyes.

Immunological System Antimitochondrial antibodies.

Liver and Biliary System Cholestasis with or without jaundice.

Musculo-Skeletal System Muscle cramps; toxic myopathy.

Respiratory System Bronchospasm.

Skin and Appendages Rashes of various types, such as generalized maculo-papular; lichenoid; urticarial; bullous lichen planus; psoriaform; facial erythema; Peyronie's disease; reversible alopecia.

Urinary System Difficulty in micturition, including acute urinary bladder retention.

Following approval for marketing in the United Kingdom, a monitored release survey involving approximately 6,800 patients was conducted for further safety and efficacy evaluation of this product. Results of this survey indicate that the type, severity, and incidence of adverse effects were comparable to those cited above.

Potential Adverse Effects

In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents.

Central Nervous System Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular Intensification of AV block. See **CONTRAINDICATIONS**.

Allergic Fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic Agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura.

Gastrointestinal Mesenteric artery thrombosis; ischemic colitis.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with labetalol HCl.

Clinical laboratory tests: There have been reversible increases of serum transaminases in 4% of patients treated with labetalol HCl and tested, and more rarely, reversible increases in blood urea.

OVERDOSAGE

Overdosage with NORMODYNE (labetalol HCl) Tablets causes excessive hypotension which is posture sensitive, and sometimes, excessive bradycardia. Patients should be laid supine and their legs raised if necessary to improve the blood supply to the brain. The following additional measures should be employed if necessary: *Excessive bradycardia* — administer atropine (3.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously. *Cardiac failure* — administer a digitalis glycoside and a diuretic. *Hypotension* — administer vasopressors, e.g., norepinephrine. There is pharmacological evidence that norepinephrine may be the drug of choice. *Bronchospasm* — administer a $beta_2$-stimulating agent and/or a theophylline preparation.

Gastric lavage or pharmacologically induced emesis (using syrup of ipecac) is useful for removal of the drug shortly after ingestion. Labetalol HCl can be removed from the general circulation by hemodialysis.

The oral LD_{50} value of labetalol HCl in the mouse is approximately 600 mg/kg and in the rat is greater than 2 gm/kg. The intravenous LD_{50} in these species is 50 to 60 mg/kg.

DOSAGE AND ADMINISTRATION

DOSAGE MUST BE INDIVIDUALIZED. The recommended initial dose is 100 mg twice daily whether used alone or added to a diuretic regimen. After 2 or 3 days, using standing blood pressure as an indicator, dosage may be titrated in increments of 100 mg bid every 2 or 3 days. The usual maintenance dosage of labetalol HCl is between 200 and 400 mg twice daily.

Since the full antihypertensive effect of labetalol HCl is usually seen within the first one to three hours of the initial dose or dose increment, the assurance of a lack of an exaggerated hypotensive response can be clinically established in the office setting. The antihypertensive effects of continued dosing can be measured at subsequent visits, approximately 12 hours after a dose, to determine whether further titration is necessary.

Patients with severe hypertension may require from 1200 mg to 2400 mg per day, with or without thiazide diuretics. Should side effects (principally nausea or dizziness) occur with these doses administered bid, the same total daily dose administered three times daily may improve tolerability and facilitate further titration. Titration increments should not exceed 200 mg twice daily.

When a diuretic is added, an additive antihypertensive effect can be expected. In some cases this may necessitate a labetalol HCl dosage adjustment. As with most antihypertensive drugs, optimal dosages of NORMODYNE Tablets are usually lower in patients also receiving a diuretic.

When transferring patients from other antihypertensive drugs, NORMODYNE Tablets should be introduced as recommended and the dosage of the existing therapy progressively decreased.

HOW SUPPLIED

NORMODYNE (labetalol HCl) Tablets, 100 mg, light-brown, round, scored, film-coated tablets engraved on one side with Schering and product identification numbers 244, and on the other side the number 100 for the strength and "NORMODYNE"; bottles of 100 (NDC-0085-0244-04), 500 (NDC-0085-0244-05), and box of 100 for unit-dose dispensing (NDC-0085-0244-08).

NORMODYNE (labetalol HCl) Tablets, 200 mg, white, round, scored, film-coated tablets engraved on one side with Schering and product identification numbers 752, and on the other side the number 200 for the strength and "NORMODYNE"; bottles of 100 (NDC-0085-0752-04), 500 (NDC-0085-0752-05), box of 100 for unit-dose dispensing (NDC-0085-0752-08), and Patient Calendar Package of 56 (4 bottles of 14 tablets) (NDC-0085-0752-03).

NORMODYNE (labetalol HCl) Tablets, 300 mg, blue, round, film-coated tablets engraved on one side with Schering and product identification numbers 438, and on the other side the number 300 for the strength and "NORMODYNE"; bottles of 100 (NDC-0085-0438-03), 500 (NDC-0085-0438-05), box of 100 for unit-dose dispensing (NDC-0085-0438-06), and Patient Calendar Package of 56 (4 bottles of 14 tablets) (NDC-0085-0438-02).

NORMODYNE (labetalol HCl) Tablets should be stored between 2° and 30°C (36° and 86°F).

NORMODYNE (labetalol HCl) Tablets in the unit-dose boxes should be protected from excessive moisture.

For complete prescribing information, please consult package insert.

With our system diagnostics, Intermedics gives you actual operating system parameters for improved pacemaker/patient monitoring.

Measured cell voltage and impedance let you know the battery status – even before elective replacement indication. Measured lead impedance helps you spot potential lead difficulties – before they become clinical problems. System diagnostics also gives you data to maintain a safety margin for capture, while helping you to maximize device longevity.

Intermedics System Diagnostics gives you inside information, before your patient needs outside help.

Displayed on the Rx2000 programmer screen or printed for your files, this total pacing profile gives you sound information on which to base clinical decisions.

Intermedics diagnostics is all this and quite a bit more. For full information on our system and patient diagnostics, call your sales representative. Or call us toll-free at 1-800-231-2330. (In Texas, 1-800-392-3726.) We'll give you all the inside information.

For **every** professional with an interest in Exercise and the Heart.

EXERCISE in Cardiovascular Health and Disease

Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS.

This comprehensive work covers every aspect of exercise and its role in Diagnosis, Treatment, and Prevention of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

Yorke Medical Books
Box C-757, Brooklyn, New York 11205 AJCK5

Please send me a copy of EXERCISE in Cardiovascular Health and Disease for 30 days free examination and use. If I decide to keep it, your invoice will be honored ($42.50 plus shipping cost). Otherwise, the book will be returned for full refund or credit.

☐ Full payment enclosed, publisher pays shipping.
☐ Please bill me, plus cost of shipping.
☐ Charge my credit card: ☐ MasterCard ☐ Visa.

Intermedics Patient Diagnostics gives you pacemaker history, so you can control the future.

Monitoring the pacemaker/patient interaction is the key to providing optimal pacing therapy. Intermedics patient diagnostics lets you fine-tune your therapy by providing a beat-by-beat record of cardiac activity. Including paced and sensed events, number of premature ventricular events, and the number of times the pacemaker reached its ventricular tracking limit.

With up to six months of memory storage, you can optimize programmable parameters, evaluate the effects of drug therapy, and judge the patient's pattern of pacemaker utilization based on quantitative data.

To help in your clinical decisions and record keeping, diagnostic information is displayed on the Rx2000 programmer screen, and can be printed for your files.

But Intermedics diagnostics is even more than this. For complete information on our patient and system diagnostics, call your sales representative. Or call us toll-free at 1-800-231-2330. (In Texas, 1-800-392-3726.) We'll put all the information in your control.

(Corona). Digital and Corona readings correlated well with subjective interpretation of film ($r > 0.85$ for both). Corona markedly improved intraobserver ($p < 0.005$) and interobserver ($p < 0.001$) reproducibility. Corona less frequently misclassified individual observations than did film when categories of less than 50, 50 to 75 and more than 75% diameter stenosis were used (3.7% vs 31.5%, $p < 0.001$). Our results suggest that automatic measurement of coronary stenosis is accurate compared with measurements by a group of experienced angiographers, and for the practical purpose of clinical decision making, it eliminates intraobserver and interobserver variability.

724 Comparison of Buccal Nitroglycerin and Oral Isosorbide Dinitrate for Nitrate Tolerance in Stable Angina Pectoris

JOHN O. PARKER, KAREN A. VANKOUGHNETT, and BERNICE FARRELL

Sixteen patients with chronic, stable exertional angina pectoris were studied to compare the hemodynamic and antianginal effects of buccal nitroglycerin (GTN) and oral isosorbide dinitrate (ISDN). During acute therapy, both buccal GTN (3 mg) and oral ISDN (30 mg) decreased systolic blood pressure at rest for 5 hours. During sustained 3-times-daily therapy with buccal GTN and 4-times-daily therapy with oral ISDN, no significant changes were seen in systolic blood pressure at rest. Treadmill walking time increased significantly over the 5-hour period during acute and sustained administration of buccal GTN. The acute response to oral ISDN was similar to that with buccal GTN, but during sustained therapy with ISDN the improvement in treadmill walking time was diminished and persisted for only 1 hour. This investigation suggests that nitrate tolerance develops with 4-times-daily therapy with oral ISDN but not during 3-times-daily therapy with buccal GTN.

729 Collateral Flow in Patients with Acute Myocardial Infarction

WILLIAM D. NITZBERG, HRUDAYA P. NATH, WILLIAM J. ROGERS, WILLIAM P. HOOD, Jr., PATRICK L. WHITLOW, RUSSELL REEVES, and WILLIAM A. BAXLEY

Using a system developed to assess collaterals in a semiquantitative fashion from coronary arteriograms, infarct-zone collaterals were examined at the time of and 2 weeks after acute myocardial infarction in 53 patients undergoing emergency angiography and reperfusion interventions. Baseline collaterals were sparse; collaterals were more extensive 2 weeks after acute myocardial infarction, and they increased primarily in patients with occluded infarct-related arteries at follow-up angiography. Improvement in global ejection fraction at repeat angiography among patients with occluded infarct-related vessels during acute myocardial infarction tended to be associated with higher baseline collaterals scores.

737 Frequency and Significance of Induced Sustained Ventricular Tachycardia or Fibrillation Two Weeks After Acute Myocardial Infarction

ANIL K. BHANDARI, JEFFREY S. ROSE, ADAM KOTLEWSKI, SHAHBUDIN H. RAHIMTOOLA, and DELON WU

Electrophysiologic stimulation studies, 24-hour ambulatory electrocardiographic monitoring and angiographic evaluations were prospectively performed in 45 patients 9 to 21 days after acute transmural myocardial infarction. Of 45 patients, 20 (44%) had induction of sustained ventricular tachycardia or fibrillation (group I). These patients had more severe wall motion abnormalities and a higher incidence of left ventricular aneurysms than the 25 patients with no inducible sustained ventricular tachyarrhythmias (group II). During a mean follow-up of 10 ± 3 months, 1 patient in each group died suddenly and 1 patient in group I had spontaneous sustained ventricular tachycardia. Electrical induction of sustained ventricular arrhythmias is common 2 weeks after acute infarction, but appears to be of limited prognostic significance.

742 Crossover from Intravenous to Transdermal Nitroglycerin Therapy in Unstable Angina Pectoris

SHU-GUANG LIN and JOHN T. FLAHERTY

The present study was designed to examine the safety and efficacy of titrating intravenous (i.v.) nitroglycerin to a fixed hemodynamic endpoint as the initial therapy for patients admitted to a coronary care unit for medically refractory unstable angina, and to test the hypothesis that patients, responding to the addition of i.v. nitroglycerin

dications: Quinidex Extentabs are dicated in the treatment of: premature rial and ventricular contractions, roxysmal atrial tachycardia, paroxmal A-V junctional rhythm, atrial flut-, paroxysmal atrial fibrillation, tablished atrial fibrillation when erapy is appropriate, paroxysmal ventcular tachycardia when not associated th complete heartblock, maintenance erapy after electrical conversion of rial fibrillation and/or flutter.

ontraindications: Intraventricular nduction defects. A-V block. Idiosyasy or hypersensitivity.

Aberrant impulses and abnormal ythms due to escape mechanisms ould not be treated with quinidine.

Warning: In the treatment of atrial flut-, reversion to sinus rhythm may be eceded by a progressive reduction in e degree of A-V block to a 1:1 ratio and sulting extremely rapid ventricular rate.

recautions: All the precautions apply g to regular quinidine therapy apply to is product. Use with care in patients th severe congestive failure, renal inefficiency or with digitalis intoxication. Patients should be carefully observed r sign of toxicity: e.g., (1) allergy or osyncrasy, such as febrile reactions, in eruptions, and thrombocytopenia xtremely rare); (2) "cinchonism," such tinnitus, blurred vision, dizziness, htheadedness, and tremor; (3) G-I mptoms (nausea, vomiting, diarrhea, d colic); (4) cardiotoxic effects such as ntricular extrasystoles occurring at a e of one or more every 6 normal beats, increase of the QRS complex of 50% more, a complete A-V block, or ventcular tachycardia.

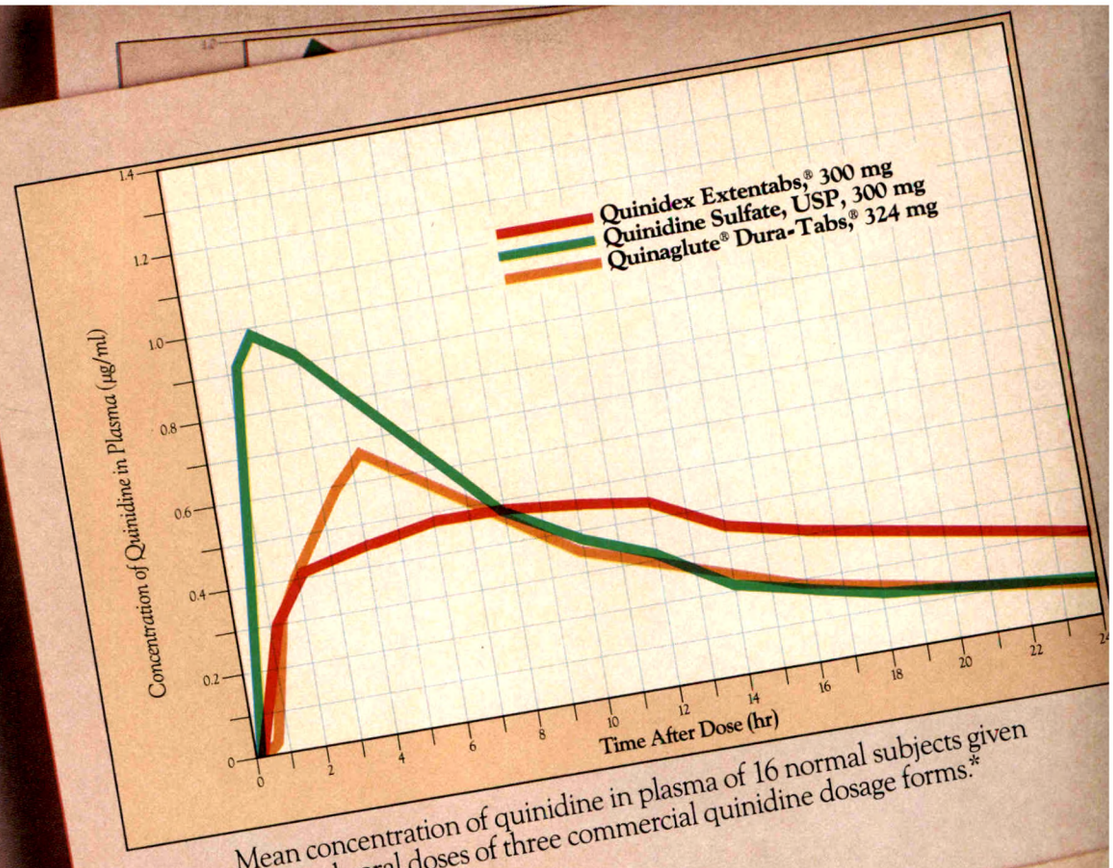
OTE: The development of "cinchosm" is not usually sufficient reason for rminating quinidine therapy. G-I mptoms can also be minimized by ving the drug with food.

dverse Reactions: Cases of quinine-induced hypoprothrombinemic morrhage in patients on chronic ticoagulant drug therapy have been ported.

osage: One or two tablets every 8 to hours.

ow Supplied: White, sugar-coated tentabs in bottles of 100 (NDC 31-6649-63), 250 (NDC 0031-6649-67) d Dis-Co® unit dose packs of 100 DC 0031-6649-64).

Rev. May 1984



Mean concentration of quinidine in plasma of 16 normal subjects given single oral doses of three commercial quinidine dosage forms.*

Consider The Evidence For Quinidex (Quinidine Sulfate, USP), 300 mg Extentabs®

- The convenience of b.i.d. dosage*
- Up to 12 hours of smooth, sustained release
- Relative bioavailability equal to Quinidine Sulfate Tablets, USP
- Contains 48 mg more active quinidine than the leading gluconate product

*Some patients may require a t.i.d. dosage schedule.

For the proof, ask your Robins representative for a copy of the controlled crossover study. Or write S. Tisdale, M.D., 1211 Sherwood Avenue, Richmond, Va. 23220.

to their previous antianginal regimen, could be crossed over to nitroglycerin administered by one of the new transdermal delivery systems. Nine patients had a nitroglycerin infusion titrated to a 10% reduction in mean arterial pressure, which resulted in cessation of episodes of chest pain at rest in all 9. Subsequently, this treatment strategy was tested in 17 consecutive patients treated in our coronary care unit during a 1-month period for unstable angina. Ten of 15 successfully treated patients had an ischemia as the cause of their chest pain documented by cardiac catheterization and no change in antianginal or vasoactive drugs during crossover to transdermal therapy. In 4.8 ± 0.9 hours, all 10 patients were tapered off i.v. nitroglycerin (84 ± 74 μg/min, range 10 to 200) and crossed over in a stepwise fashion to transdermal nitroglycerin patches (22.5 ± 10 mg/24 hours, range 5 to 40), while maintaining the mean arterial pressure reduction achieved with i.v. therapy. Among these 10 patients, 7 had no further pain episodes throughout the remainder of their hospitalization. Two patients had a single episode of chest pain, after transient interruption of transdermal nitroglycerin therapy in 1 and transient reduction of the transdermal dose in the other. These results suggest that i.v. nitroglycerin is safe and effective treatment for patients with unstable angina admitted to a coronary care unit, and that the new transdermal nitroglycerin delivery systems successfully maintain these beneficial effects.

749 Ischemia During Angioplasty After Streptokinase: A Marker of Myocardial Salvage

LOWELL F. SATLER, CHARLES E. RACKLEY, CURTIS E. GREEN, RANDOLPH S. PALLAS, DAVID L. PEARLE, ALBERT A. DEL NEGRO, and KENNETH M. KENT

Thrombolytic therapy in acute myocardial infarction has not clearly demonstrated myocardial salvage as assessed by enzymatic, electrocardiographic, or regional wall motion evaluation of the left ventricle. After successful reperfusion, however, patients frequently experience recurrent episodes of chest pain, presumably owing to transient reocclusion of the infarct vessel. To recognize salvaged myocardium, the effects of coronary angioplasty soon after thrombolytic therapy were reviewed. Controlled reocclusion of the infarct vessel with a balloon catheter resulted in electrocardiographic or ischemic changes in 21 of 55 patients. These ischemic changes suggest the presence of persistently viable, salvaged myocardium in the distribution of the reperfused infarct vessel.

753 Evaluation of Methods of Measurement and Estimation of Left Ventricular Function After Acute Myocardial Infarction

MICHAEL G. JONES, BARRY W. RAMO, GILBERT L. RAFF, TOMOAKI HINOHARA, and GALEN S. WAGNER

Multiple gated blood pool imaging and single-plane contrast ventriculography were used to obtain 2 independent measures of left ventricular (LV) ejection fraction (EF) in each of 21 patients seen 2 to 6 weeks after their first acute myocardial infarction (AMI). These measures were then compared with the extent of myocardial necrosis estimated from a standard 12-lead electrocardiogram using the complete Selvester QRS scoring system. Correlation coefficients between the 2 measures of LVEF were similar to those previously reported for non-AMI populations. A QRS score of 4 or less achieved 100% specificity and a score of 8 or less, 100% sensitivity for predicting an LVEF greater than 40%. Thus, the Selvester QRS scoring system may be of value in identifying patients with or without markedly impaired LVEF. This risk stratification may be important in reaching optimal post-AMI therapeutic decisions.

757 Infections in a Coronary Care Unit

WINSTON A. SCHANDORF, RICHARD B. BROWN, MICHAEL SANDS, and DAVID HOSMER

All infections within an active coronary care unit (CCU) were analyzed over a 3-year period to ascertain rates, outcomes, pathogens and infection sites. Two hundred thirty-six infections were documented in 200 patients. Infection rates were 5 and 2% for total and CCU-acquired infections, respectively. The latter accounted for 11% of nosocomial infections that occurred within all critical care areas surveyed. Lower respiratory and urinary tract infections were most commonly noted, with *E. coli*, *S. aureus* and klebsiella-enterobacter-serratia most usually implicated. Mortality among patients with infections was 31%, compared with 8 to 12% in those without infections. Patients with fewer respiratory infections or primary bacteremias had a higher mortality rate than

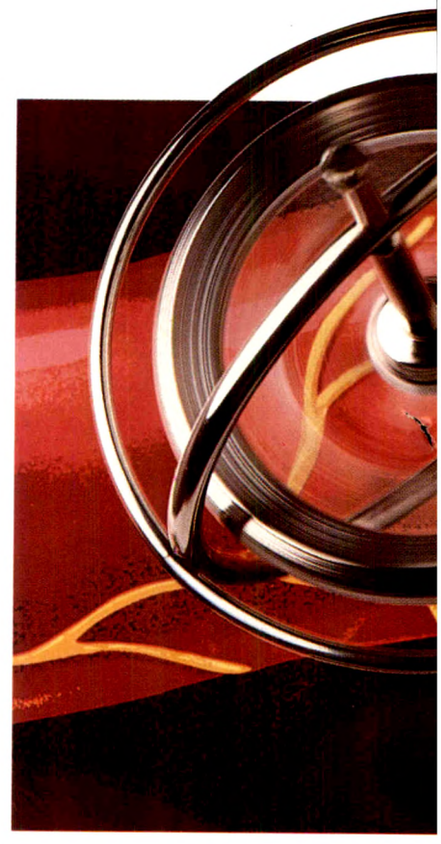
BALANCED CALCIUM CHANNEL BLOCKADE

CARDIZEM®
(diltiazem HCl)

CARDIZEM® (diltiazem HCl): with a low incidence

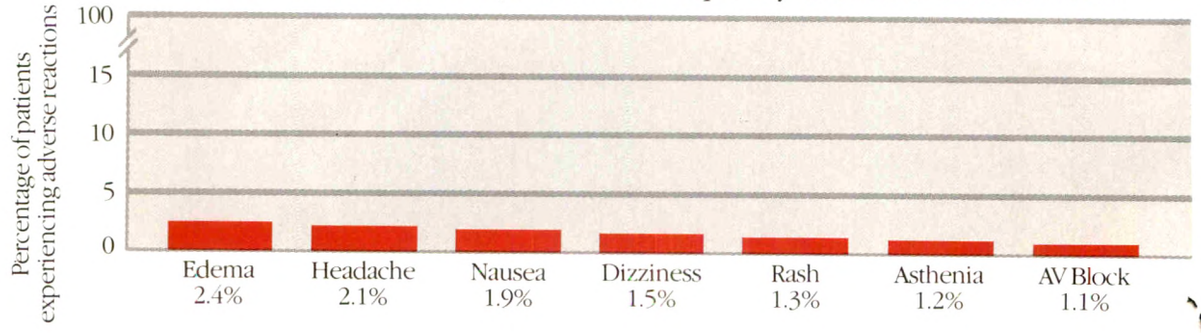
In the treatment of angina pectoris, calcium channel blockers have been found to be potent coronary vasodilators. And, due to its balanced hemodynamic profile, CARDIZEM® (diltiazem HCl) produces a low incidence of side effects, thus contributing to the patient's sense of well-being.

"The lack of significant adverse effects with diltiazem appears to correlate with the high rate of acceptance of the drug by patients and the drug's safety in both short- and long-term use."[1]



Low incidence of side effects

The adverse reactions reported most frequently with Cardizem have been:



In many cases, the relationship to Cardizem has not been established.

In placebo-controlled US trials, the incidence of adverse reactions reported during Cardizem therapy was not greater than that reported during placebo therapy.

For other adverse reactions infrequently reported (<1.0%), see brief summary of prescribing information on last page of this ad.

a balance of effectiveness of side effects

Increases exercise tolerance*

CARDIZEM® (diltiazem HCl) allows patients to significantly prolong exercise tolerance even in demanding Bruce protocol exercise tests.[2] In time to onset of pain, control patients averaged 8.0 minutes; Cardizem patients averaged 9.8 minutes.

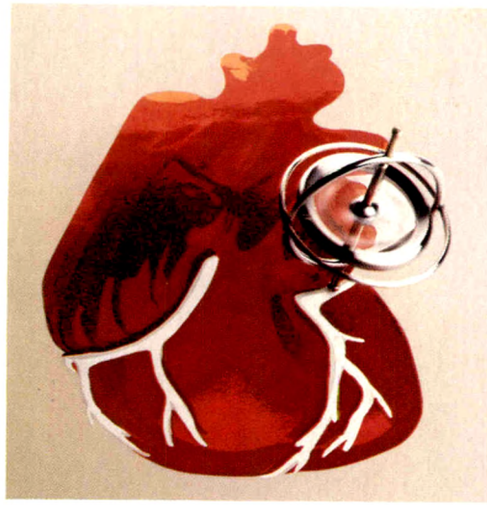
*Cardizem is indicated in the treatment of chronic stable angina (classic effort-associated angina) and angina due to coronary artery spasm.

Reduces angina attack frequency*

42% to 46% decrease in effort angina attacks reported in multicenter study.[3]

CARDIZEM®
(diltiazem HCl)

The balanced calcium channel blocker



CARDIZEM®
(diltiazem HCl)

Beneficial aspects of Cardizem therapy

- Increases coronary blood flow
- Decreases afterload and blood pressure
- Decreases heart rate
- Can be used alone or in combination with other antianginals

cardizem®
(diltiazem HCl)
30 mg and 60 mg tablets

BRIEF SUMMARY

CARDIZEM® (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist).

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina. CARDIZEM has been effective in controlled trials in reducing angina frequency and increasing exercise tolerance.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (six of 1243 patients for 0.48%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** In rare instances, patients receiving CARDIZEM have exhibited reversible acute hepatic injury as evidenced by moderate to extreme elevations of liver enzymes. (See PRECAUTIONS and ADVERSE REACTIONS.)

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

Controlled and uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities. In healthy volunteers, diltiazem has been shown to increase serum digoxin levels up to 20%.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on an mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

The following represent occurrences observed in clinical studies which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are: edema (2.4%), headache (2.1%), nausea (1.9%), dizziness (1.5%), rash (1.3%), asthenia (1.2%), AV block (1.1%). In addition, the following events were reported infrequently (less than 1%) with the order of presentation corresponding to the relative frequency of occurrence.

Cardiovascular:	Flushing, arrhythmia, hypotension, bradycardia, palpitations, congestive heart failure, syncope.
Nervous System:	Paresthesia, nervousness, somnolence, tremor, insomnia, hallucinations, and amnesia.
Gastrointestinal:	Constipation, dyspepsia, diarrhea, vomiting, mild elevations of alkaline phosphatase, SGOT, SGPT, and LDH.
Dermatologic:	Pruritus, petechiae, urticaria, photosensitivity.
Other:	Polyuria, nocturia.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

The following postmarketing events have been reported infrequently in patients receiving CARDIZEM: erythema multiforme; leukopenia; and extreme elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK. However, a definitive cause and effect between these events and CARDIZEM therapy is yet to be established.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experience with oral diltiazem has been limited. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50}'s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. Although individual patients may respond to any dosage level, the average optimum dosage range appears to be 180 to 240 mg/day. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents:

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

CARDIZEM 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47) and in Unit Dose Identification Paks of 100 (NDC 0088-1771-49). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47) and in Unit Dose Identification Paks of 100 (NDC 0088-1772-49). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

The American Journal of Cardiology does more than just print the best in authoritative articles on cardiovascular treatment. Now it puts them on videotape.

Hosted by Editor-in-Chief William C. Roberts, MD, *AJC Video Report* will feature lively, highly-visualized discussions with noted cardiovascular specialists and authors of the most important articles appearing each month in *The American Journal of Cardiology.* And it will extend the utility of the articles by exploring their application in clinical practice.

Each of the 45 minute videocassettes will feature a special guest panelist as well as the guest authors discussing:

• Coronary Heart Disease • Arrhythmias and Conduction Disturbances • Systemic Hypertension • Congestive Heart Failure • Valvular Heart Disease • Cardiomyopathy • Congenital Heart Disease • Cardiovascular Pharmacology and • Experimental Studies

AJC Video Report will be produced on a regular monthly basis starting January, 1986.

TO RECEIVE every copy of AJC Video Report—at the special introductory subscription price of $395* for 12 cassettes—complete this coupon and send it to: Joyce Sturges, *AJC Video Report,* The Yorke Medical Group, 875 Third Avenue, New York, N.Y. 10022. Or call (212) 605-9549.

persons infected at other sites ($p < 0.001$). Infections are seen in almost 5% of CCU patients. Mortality rates in infected patients may be 3 times higher than in the general CCU population. This study provides data against which other similar institutions can gauge their CCU infection rates

METHODS

761 Determination of Left Ventricular Mass Using Single-Photon Emission Computed Tomography

CHRISTOPHER L. WOLFE, DONALD E. JANSEN, JAMES R. CORBETT, KIRK LIPSCOMB, GREGORY GABLIANI, NEIL FILIPCHUK, GREGORY REDISH, SAMUEL E. LEWIS, and JAMES T. WILLERSON

This study tested the hypothesis that single-photon emission computed tomography (SPECT) accurately measures left ventricular (LV) mass in humans. SPECT measurements of LV mass were compared with LV mass determined by cineangiography in 12 patients. There was good correlation between LV mass determined by SPECT and by cineangiography ($r = 0.82$, root-mean-square deviation from regression = 24.7).

764 Analysis of Factors Affecting the Variability of Fick Versus Indicator Dilution Measurements of Cardiac Output

L. DAVID HILLIS, BRIAN G. FIRTH, and MICHAEL D. WINNIFORD

This study was performed to assess the relation between Fick and indicator dilution measurements of cardiac output (CO) in a large number of subjects, and to evaluate this relation in patients with a low CO, a high CO and left-sided regurgitation. In 808 patients, CO was measured by Fick and either thermodilution (right atrium to pulmonary artery) ($n = 252$) or indocyanine green dye (pulmonary artery to systemic artery) ($n = 556$). There was good agreement between Fick and both indicator dilution techniques. The disparity between Fick and indicator dilution was increased in patients with a low CO (less than 2 liters/min/m^2) ($n = 152$) and aortic or mitral regurgitation ($n = 83$). In these groups, the disparity between Fick and thermodilution was not increased, but the disparity between Fick and dye was exaggerated. Thus, thermodilution is preferable to indocyanine green dye in patients with a low CO or those with left-sided regurgitation.

769 Effect of Damped Sine-Wave Shocks on Catheter Dielectric Strength

GUST H. BARDY, FERNANDO COLTORTI, TOM D. IVEY, DAN YERKOVICH, and H. LEON GREENE

This study evaluated the ability of 24 new standard tripolar and quadripolar catheters to withstand a single damped sinusoidal shock delivered by a standard defibrillator. The schema for energy delivery was meant to simulate possible clinical practices. Delivered peak voltage and current were measured during each shock. Each electrode was examined for pitting and changes in line resistance as a consequence of the shock. Electrode pitting occurred on all selected anodal poles. However, it also was found on "unsolicited" electrodes from 7 catheters, indicating that current had followed unanticipated routes. Electrode line resistance was unmeasurable in 6 of these 7 inappropriately pitted electrodes. Delivered peak voltage and post-shock catheter dielectric strength depended on the manner of energy delivery. To simulate a posterior septal accessory pathway ablation procedure a shock was delivered to 2 proximal (anodal) poles in 16 quadripolar catheters (8 received 200 J and 8 received 360 J). Delivered peak voltage was 3,125 ± 362 V for the 200-J shock and 4,100 ± 160 V for the 360-J shock. Post-shock catheter dielectric strength for the 200- and 360-J shock was 1,425 ± 826 V and 601 ± 707 V, respectively. This was significantly lower than peak delivered voltage ($p < 0.001$ for either energy). To simulate His bundle or VT focus ablation, 8 tripolar catheters each received a single 200-J shock to the tip electrode. This resulted in a delivered peak voltage of 2,900 ± 351 V, compared with a post-shock dielectric strength of 1,325 ± 1,320 V ($p < 0.002$). Thus, standard catheters cannot control current flow adequately during a single high-energy shock because of inadequate dielectric strength. After the first shock an already inadequate dielectric strength deteriorates and increases the likelihood of current leakage with each subsequent shock.

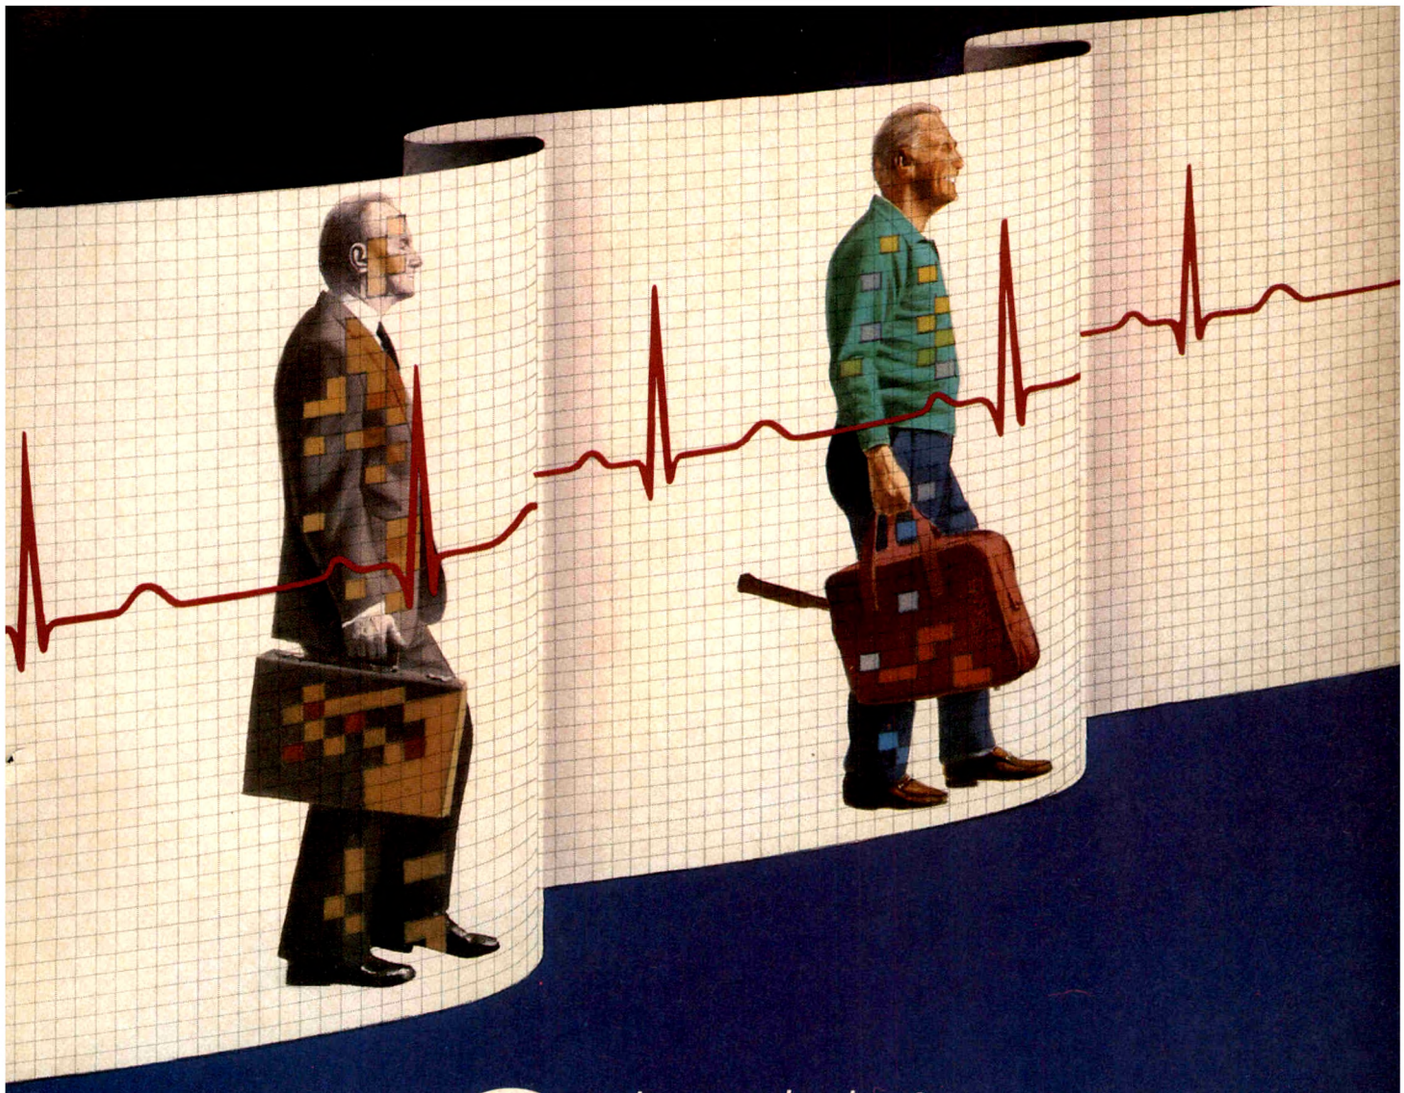
BERLEX Laboratories, Inc., Wayne, New Jersey 07470



dura-tabs® SUSTAINED-RELEASE TABLETS 324 mg

Quinaglute®

quinidine gluconate

- Continuous arrhythmia control
- Well tolerated in long-term therapy[1]
- Less GI upset than with quinidine sulfate[2]
- B.I.D.* dosage for uninterrupted protection

Start the oral agent he can live with

*Some patients may require more frequent (t.i.d.) dosing

Please turn page for brief summary of prescribing information.

References: 1. Selzer A: *Heart Lung* 1982;11:20-23.
2. Podrid P: *Patient Care* 1981;15:100-132.

INDICATIONS AND USAGE: Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:
1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock).
2. Junctional (nodal) arrhythmias: A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).
CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.
WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine. 2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered. 3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring. 4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals. 5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity. 7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal. 8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.
PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk. *Information for Patients:* As with all solid oral medications, Quinaglute (quinidine gluconate) Dura-Tabs (sustained-release tablets) should be taken with an adequate amount of fluid, preferably in an upright position, to facilitate swallowing.

Drug Interactions: *Drug*	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.
Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.
Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.
Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.
ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea. Less frequently encountered adverse reactions:
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.

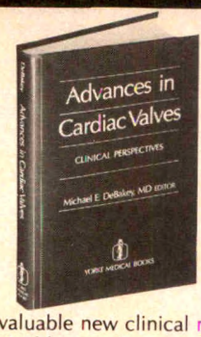
The Most Extensive Compilation of Information on Heart Valve Replacement Available Today!



Advances in Cardiac Valves
Clinical Perspectives

edited by
Michael E. DeBakey, MD
0-914316-40-0, 1983, 274pp., $35.00

This valuable new clinical reference provides a detailed update on many aspects of mechanical heart valve prostheses, including hemodynamics, clinical results, results in children, non-invasive assessments, special indications, and implant techniques. Each topic is presented in an easily understood style and format which facilitate the comprehension of recent developments in heart valve replacement for the busy clinician.

Each chapter is written by internationally respected physicians and medical scientists each of whom is pre-eminent in his field. All of the information has been co-ordinated by Dr. DeBakey to produce a very readable and informative volume on the state-of-the-art of heart valve replacement with mechanical prostheses. No cardiologist, cardiovascular surgeon, internist, or bioengineer can afford *not* to be knowledgeable about the information in this book.

773 **Value of Intraoperative Left Ventricular Microbubbles Detected by Transesophageal Two-Dimensional Echocardiography in Predicting Neurologic Outcome After Cardiac Operations**

ERIC J. TOPOL, LINDA S. HUMPHREY, A. MICHAEL BORKON, WILLIAM A. BAUMGARTNER, DEBRA L. DORSEY, BRUCE A. REITZ, and JAMES L. WEISS

To determine whether the presence or absence of left ventricular intracavitary microbubbles during cardiac surgery predicts neurologic outcome, 82 patients undergoing cardiac surgery were studied with transesophageal 2-dimensional echocardiography. Microbubbles were detected after cardiopulmonary bypass in 34 patients (41%) and were more often found in those who underwent valvular or intracardiac manipulations than in those who underwent coronary revascularization, 30 of 40 vs 4 of 42 patients, respectively ($p < 0.001$). When dense microbubbles were identified (22 of 34 patients), mechanical attempts to eradicate them were not successful. Postoperative follow-up did not reveal new focal neurologic deficits. However, a prolonged confusional state (longer than 72 hours) occurred in 4 of 48 patients with no detectable microbubbles and 3 of 34 patients with microbubbles (difference not significant). Thus, intracavitary left ventricular microbubbles are detected frequently during cardiac surgery, particularly during valve replacement, but are not predictive of postoperative neurologic complications.

776 **Right Ventricular Ejection Fraction Measured by First-Pass Intravenous Krypton-81m: Reproducibility and Comparison with Technetium-99m**

DEAN F. WONG, T.K. NATARAJAN, WARREN SUMMER, PAUL A. TIBBITS, THOMAS BECK, DANIEL KOLLER, WAYNE KASECAMP, JAMES LAMB, JOSEPH OLYNYK, MARY SUE PHILP, MARSHALL BRYAN, and HENRY N. WAGNER, Jr.

Right ventricular ejection fraction was studied using intravenous first-pass krypton-81m in 22 subjects. This technique was compared with the standard technetium-99m method. Krypton-81m, which has a 13-second half-life, offers the advantage of multiple replicate studies within minutes of each other. The study showed good correlation of krypton-81m with the standard technique, but krypton-81m results in considerably less radiation exposure.

781 **Measurement of Left Ventricular Volume Using Single-Photon Emission Computed Tomography**

GARY R. CAPUTO, MICHAEL M. GRAHAM, KIRK D. BRUST, J. WARD KENNEDY, and WIL B. NELP

Left ventricular (LV) volume was measured using single-photon emission computed tomography (SPECT) of the cardiac blood pool. The tomographic slices were used to determine the counts per milliliter in the center of the left ventricle and total LV counts, which were used to derive mean LV volume. End-diastolic and end-systolic volumes were calculated from the mean volume using the LV time-activity curve from planar gated blood pool images. Phantom evaluation with simulated LV volumes (50 to 400 ml) showed excellent accuracy. For clinical validation, the results from 30 patients were compared with single-plane cineangiography. For end-diastolic and end-systolic volumes combined, the correlation with cineangiography showed a standard error of the estimate of 24 ml and 14 ml, respectively. This relatively simple, SPECT-based technique is an accurate and reproducible way to measure LV volume.

For hypertensive emergency

TRANDATE®
INJECTION 20 ml, 5 mg/ml

labetalol HCl/Glaxo

The "beta-dilator"™ response: control within minutes

Action within a minute. Trandate® (labetalol HCl/Glaxo) Injection rapidly, predictably lowers blood pressure by lowering total peripheral resistance (TPR), while maintaining cardiac output.[1,2] The "beta-dilator"™ effect of simultaneous beta blockade and alpha blockade-induced vasodilation is apparent within a minute.

Rapid control. Full effect of an IV dose is apparent in 5 to 10 minutes: helps avoid hypotensive "overshoot," facilitates monitoring.

Cost control. Rapid effect may shorten hospital stay and beneficially affect costs under DRG's.

Well tolerated.* The most commonly reported adverse reactions: postural hypotension,† dizziness,† paresthesias, increased sweating and nausea.

Smooth transition to oral therapy with the same agent. Control of hypertensive crisis with Trandate Injection allows continued control on oral therapy with no need to change agents.

Trandate Injection—the "beta-dilator"™ response to hypertensive emergencies...another original product of Glaxo research.

* Patients should always be kept in a supine position during IV drug administration. See **DOSAGE AND ADMINISTRATION** section of Prescribing Information before initiating therapy.

† The episodes of postural hypotension and dizziness occurred primarily in one study in which patients were placed in an upright position within three hours of dosing for evaluation.

For a discussion of **ADVERSE REACTIONS**, please see Brief Summary of Prescribing Information on the last page of this advertisement.

Glaxo

For hypertensive emergency

TRANDATE® INJECTION 20 ml, 5 mg/ml

labetalol HCl/Glaxo

The "beta-dilator"™ response: control within minutes

- Trandate Injection can be administered as repeated IV injections, or by continuous infusion
- After initial dosing, further blood pressure reductions can be achieved with additional injections or by slow continuous infusion
- Discontinue Trandate Injection when blood pressure goal is achieved—when supine blood pressure has begun to rise, oral therapy may be initiated
- Patients should be kept in the supine position during IV drug administration. See **DOSAGE AND ADMINISTRATION** section of Prescribing Information before initiating therapy

For a discussion of **ADVERSE REACTIONS**, please see Brief Summary of Prescribing Information on the last page of this advertisement.

TRANDATE® Injection
(labetalol hydrochloride)

BRIEF SUMMARY OF PRESCRIBING INFORMATION

INDICATIONS AND USAGE: TRANDATE® (labetalol HCl) Injection is indicated for control of blood pressure in severe hypertension.

CONTRAINDICATIONS: TRANDATE® Injection is contraindicated in bronchial asthma, overt cardiac failure, greater than first degree heart block, cardiogenic shock, and severe bradycardia (see **WARNINGS**).

WARNINGS: Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure. Beta blockade carries a potential hazard of further depressing myocardial contractility and precipitating more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, labetalol HCl can be used with caution in patients with a history of heart failure who are well-compensated. Congestive heart failure has been observed in patients receiving labetalol HCl. Labetalol HCl does not abolish the inotropic action of digitalis on heart muscle.

In Patients Without a History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitilization and diuretic, TRANDATE® therapy should be withdrawn (gradually, if possible).

Ischemic Heart Disease: Angina pectoris has not been reported upon labetalol HCl discontinuation. However, following abrupt cessation of therapy with some beta-blocking agents in patients with coronary artery disease, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Therefore, such patients should be cautioned against interruption of therapy without the physician's advice. Even in the absence of overt angina pectoris, when discontinuation of TRANDATE is planned, the patient should be carefully observed and should be advised to limit physical activity. If angina markedly worsens or acute coronary insufficiency develops, TRANDATE administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken.

Nonallergic Bronchospasm (eg, chronic bronchitis and emphysema): Since TRANDATE Injection at the usual intravenous therapeutic doses has not been studied in patients with nonallergic bronchospastic disease, it should not be used in such patients.

Pheochromocytoma: Intravenous labetalol HCl has been shown to be effective in lowering the blood pressure and relieving symptoms in patients with pheochromocytoma; higher than usual doses may be required. However, paradoxical hypertensive responses have been reported in a few patients with this tumor; therefore, use caution when administering labetalol HCl to patients with pheochromocytoma.

Diabetes Mellitus and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (eg, tachycardia) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; it may therefore be necessary to adjust the dose of antidiabetic drugs.

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial. Protracted severe hypotension and difficulty in restarting or maintaining a heartbeat have been reported with beta-blockers. The effect of labetalol HCl's alpha-adrenergic activity has not been evaluated in this setting.

A synergism between labetalol HCl and halothane anesthesia has been shown (see **Drug Interactions**).

Rapid Decreases of Blood Pressure: Caution must be observed when reducing severely elevated blood pressure. Although such findings have not been reported with intravenous labetalol HCl, a number of adverse reactions, including cerebral infarction, optic nerve infarction, angina and ischemic changes in the electrocardiogram, have been reported with other agents when severely elevated blood pressure was reduced over time courses of several hours to as long as 1 or 2 days. The desired blood pressure lowering should therefore be achieved over as long a period of time as is compatible with the patient's status.

PRECAUTIONS: General: ***Impaired hepatic function*** may diminish metabolism of TRANDATE® Injection.

Hypotension: Symptomatic postural hypotension (incidence 58%) is likely to occur if patients are tilted or allowed to assume the upright position within 3 hours of receiving TRANDATE Injection. Therefore, the patient's ability to tolerate an upright position should be established before permitting any ambulation.

Jaundice or Hepatic Dysfunction: On rare occasions, oral labetalol HCl has been associated with jaundice (both hepatic and cholestatic). It is therefore recommended that treatment with labetalol HCl be stopped immediately should a patient develop jaundice or laboratory evidence of liver injury. Both have been shown to be reversible on stopping therapy.

Information for Patients: The following information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. During and immediately following (for up to 3 hours) TRANDATE Injection, the patient should remain supine. Subsequently, the patient should be advised on how to proceed gradually to become ambulatory, and should be observed at the time of first ambulation.

When the patient is started on TRANDATE Tablets, following adequate control of blood pressure with TRANDATE Injection, appropriate directions for titration of dosage should be provided (see **DOSAGE AND ADMINISTRATION**).

As with all drugs with beta-blocking activity, certain advice to patients being treated with labetalol HCl is warranted: While no incident of the abrupt withdrawal phenomenon (exacerbation of angina pectoris) has been reported with labetalol HCl, dosing with TRANDATE Tablets should not be interrupted or discontinued without a physician's advice. Patients being treated with TRANDATE Tablets should consult a physician at any sign of impending cardiac failure. Also transient scalp tingling may occur, usually when treatment with TRANDATE Tablets is initiated (see **ADVERSE REACTIONS**).

Laboratory Tests: Routine laboratory tests are ordinarily not required before or after intravenous labetalol HCl. In patients with concomitant illnesses, such as impaired renal function, appropriate tests should be done to monitor these conditions.

Drug Interactions: Since TRANDATE (labetalol HCl) Injection may be administered to patients already being treated with other medications, including other antihypertensive agents, careful monitoring of these patients is necessary to detect and treat promptly any undesired effect from concomitant administration.

In one survey, 2.3% of patients taking labetalol HCl orally in combination with tricyclic antidepressants experienced tremor as compared to 0.7% reported to occur with labetalol HCl alone. The contribution of each of the treatments to this adverse reaction is unknown, but the possibility of a drug interaction cannot be excluded.

Drugs possessing beta-blocking properties can blunt the bronchodilator effect of beta-receptor agonist drugs in patients with bronchospasm; therefore, doses greater than the normal anti-asthmatic dose of beta-agonist bronchodilator drugs may be required.

Cimetidine has been shown to increase the bioavailability of labetalol HCl administered orally. Since this could be explained either by enhanced absorption or by an alteration of hepatic metabolism of labetalol HCl, special care should be used in establishing the dose required for blood pressure control in such patients.

Synergism has been shown between halothane anesthesia and intravenously administered labetalol HCl. During controlled hypotensive anesthesia using labetalol HCl in association with halothane, high concentrations (3% or above) of halothane should not be used because the degree of hypotension will be increased and because of the possibility of a large reduction in cardiac output and an increase in central venous pressure. The anesthesiologist should be informed when a patient is receiving labetalol HCl.

Labetalol HCl blunts the reflex tachycardia produced by nitroglycerin without preventing its hypotensive effect. If labetalol HCl is used with nitroglycerin in patients with angina pectoris, additional antihypertensive effects may occur.

Drug/Laboratory Test Interactions: The presence of a metabolite of labetalol in the urine may result in falsely increased levels of urinary catecholamines when measured by a nonspecific trihydroxyindole (THI) reaction. In screening patients suspected of having a pheochromocytoma and being treated with labetalol HCl, specific radioenzymatic or high performance liquid chromatography assay techniques should be used to determine levels of catecholamines or their metabolites.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term oral dosing studies with labetalol HCl for 18 months in mice and for 2 years in rats showed no evidence of carcinogenesis. Studies with labetalol HCl, using dominant lethal assays in rats and mice, and exposing microorganisms according to modified Ames tests, showed no evidence of mutagenesis.

Pregnancy Category C: Teratogenic studies have been performed with labetalol in rats and rabbits at oral doses up to approximately 6 and 4 times the MRHD, respectively. No reproducible evidence of fetal malformations was observed. Increased fetal resorptions were seen in both species at doses approximating the MRHD. There are no adequate and well-controlled studies in pregnant women. Labetalol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects: Infants of mothers who were treated with labetalol HCl for hypertension during pregnancy did not appear to be adversely affected by the drug. Oral administration of labetalol to rats during late gestation through weaning at doses of 2 to 4 times the MRHD caused a decrease in neonatal survival.

Labor and Delivery: Labetalol HCl given to pregnant women with hypertension did not appear to affect the usual course of labor and delivery.

Nursing Mothers: Small amounts of labetalol (approximately 0.004% of the maternal dose) are excreted in human milk. Caution should be exercised when TRANDATE® (labetalol HCl) Injection is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: TRANDATE® Injection is usually well tolerated. Most adverse effects have been mild and transient and, in controlled trials involving 92 patients, did not require labetalol HCl withdrawal. Symptomatic postural hypotension (incidence 58%) is likely to occur if patients are tilted or allowed to assume the upright position within 3 hours of receiving TRANDATE Injection. Moderate hypotension occurred in 1 of 100 patients while supine. Increased sweating was noted in 4 of 100 patients, and flushing occurred in 1 of 100 patients.

The following also were reported with TRANDATE Injection with the incidence per 100 patients as noted:

Cardiovascular System: Ventricular arrhythmia in 1.

Central and Peripheral Nervous Systems: Dizziness in 9; tingling of the scalp/skin in 7; hypoesthesia (numbness) and vertigo in 1 each.

Gastrointestinal System: Nausea in 13; vomiting in 4; dyspepsia and taste distortion in 1 each.

Metabolic Disorders: Transient increases in blood urea nitrogen and serum creatinine levels occurred in 8 of 100 patients; these were associated with drops in blood pressure, generally in patients with prior renal insufficiency.

Psychiatric Disorders: Somnolence/yawning in 3.

Respiratory System: Wheezing in 1.

Skin: Pruritus in 1.

The incidence of adverse reactions depends upon the dose of labetalol HCl. The largest experience is with oral labetalol HCl (see TRANDATE Tablet Product Information for details.) Certain of the side effects increased with increasing oral dose as shown in the table below which depicts the entire U.S. therapeutic trials data base for adverse reactions that are probably or possibly dose-related.

Labetalol HCl Daily Dose (mg)	**200**	**300**	**400**	**600**	**800**	**900**	**1200**	**1600**	**2400**
Number of Patients	522	181	606	608	503	117	411	242	175
Dizziness (%)	2	3	3	3	5	1	9	13	16
Fatigue	2	1	4	4	5	3	7	6	10
Nausea	<1	0	1	2	4	0	7	11	19
Vomiting	0	0	<1	<1	<1	0	1	2	3
Dyspepsia	1	0	2	1	1	0	2	2	4
Paresthesias	2	0	2	2	1	1	2	5	5
Nasal Stuffiness	1	1	2	2	2	2	4	5	6
Ejaculation Failure	0	2	1	2	3	0	4	3	5
Impotence	1	1	1	1	2	4	3	4	3
Edema	1	0	1	1	1	0	1	2	2

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with labetalol HCl during investigational use and extensive foreign marketing experience.

Clinical Laboratory Tests: Among patients dosed with TRANDATE Tablets, there have been reversible increases of serum transaminases in 4% of patients tested and, more rarely, reversible increases in blood urea.

OVERDOSAGE: Overdosage with TRANDATE® Injection causes excessive hypotension which is posture sensitive and, sometimes, excessive bradycardia. Patients should be laid supine and their legs raised if necessary to improve the blood supply to the brain. The following additional measures should be employed if necessary: **Excessive bradycardia**—administer atropine (3.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously. **Cardiac failure**—administer a digitalis glycoside and a diuretic. **Hypotension**—administer vasopressors, eg, norepinephrine. There is pharmacological evidence that norepinephrine may be the drug of choice. **Bronchospasm**—administer a $beta_2$-stimulating agent and/or a theophylline preparation.

If overdosage with labetalol HCl follows oral ingestion, gastric lavage or pharmacologically induced emesis (using syrup of ipecac) is useful for removal of the drug shortly after ingestion. Labetalol HCl can be removed from the general circulation by hemodialysis.

The oral LD_{50} value of labetalol HCl in the mouse is approximately 600 mg/kg and in the rat is greater than 2 g/kg. The intravenous LD_{50} in these species is 50 to 60 mg/kg.

DOSAGE AND ADMINISTRATION: Initiation of Dosing with TRANDATE Tablets: Subsequent oral dosing with TRANDATE Tablets should begin when it has been established that the supine diastolic blood pressure has begun to rise. The recommended initial dose is 200 mg, followed in 6-12 hours by an additional dose of 200 mg or 400 mg, depending on the blood pressure response. Thereafter, **inpatient titration with TRANDATE Tablets may proceed as follows:**

Inpatient Titration Instructions

Regimen	Daily Dose*
200 mg bid	400 mg
400 mg bid	800 mg
800 mg bid	1600 mg
1200 mg bid	2400 mg

*If needed, the total daily dose may be given in three divided doses.

While in the hospital, the dosage of TRANDATE (labetalol HCl) Tablets may be increased at one-day intervals to achieve the desired blood pressure reduction.

For subsequent outpatient titration or maintenance dosing see TRANDATE Tablets Product Information **DOSAGE AND ADMINISTRATION** for additional recommendations.

HOW SUPPLIED: TRANDATE® Injection, 5 mg/ml, is supplied in 20 ml (100 mg) ampules, box of 1 (NDC 0173-0350-59).

Store between 2° and 30° C (36° and 86° F.) Do not freeze.

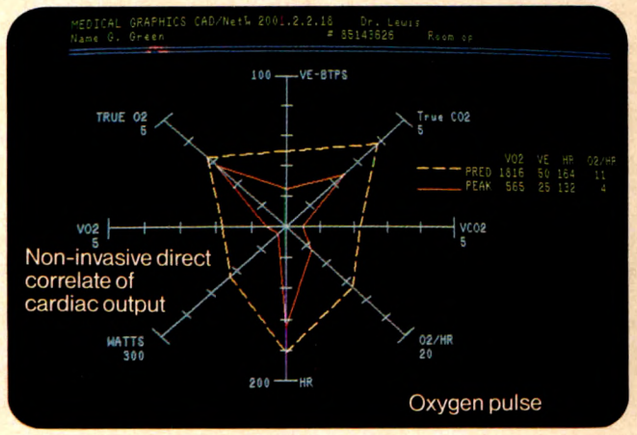
Are you obtaining only part of the information you need?

Medical Graphics System 2001 cardiodynamic imaging provides more, for comprehensive stress testing.

Stress testing is revolutionized with the CAD/Net™ Exercise Stress Testing System 2001 for non-invasive assessment of cardiac function. Real-time cardiodynamic imaging provides more clinically useful information about functional capacity and cardiac function than conventional stress testing methods.

Use the System 2001 simultaneously with your existing EKG and treadmill or cycle ergometer for:

- Early detection of coronary atherosclerosis, valvular and/or congestive heart disease (functional class impairment)
- Cardiac rehabilitation of CAB or PTCA patients (assessment of functional class improvement and patient prognosis)
- Evaluation of exercise effects of various pharmacologic agents for treatment of hypertension, congestive heart failure, coronary artery disease, arrhythmias, etc.
- Differentiation of cardiac versus pulmonary induced dyspnea and angina during exercise



Cardiodynamic Image ™

Patient Case: 56 year old with CHF. Note severe functional impairment upon limited exertion (class C), as indicated by a significantly depressed **V̇02** and **02 pulse** with compensatory HR increase.

Convenient, clinically applicable.

The automated System 2001 conducts the stress test protocol allowing physician/patient interaction. Real-time test results are immediately available on the cardiodynamic image screen in an easy to interpret graphic format. And, they can be stored for comparison with subsequent patient follow-up tests. The System 2001 saves both time and money.

The System 2001—a revolution in exercise testing.

For more information on how to maximize clinically useful data and make every stress test count, call us toll-free at **1-800-328-4138** or, return the coupon below.

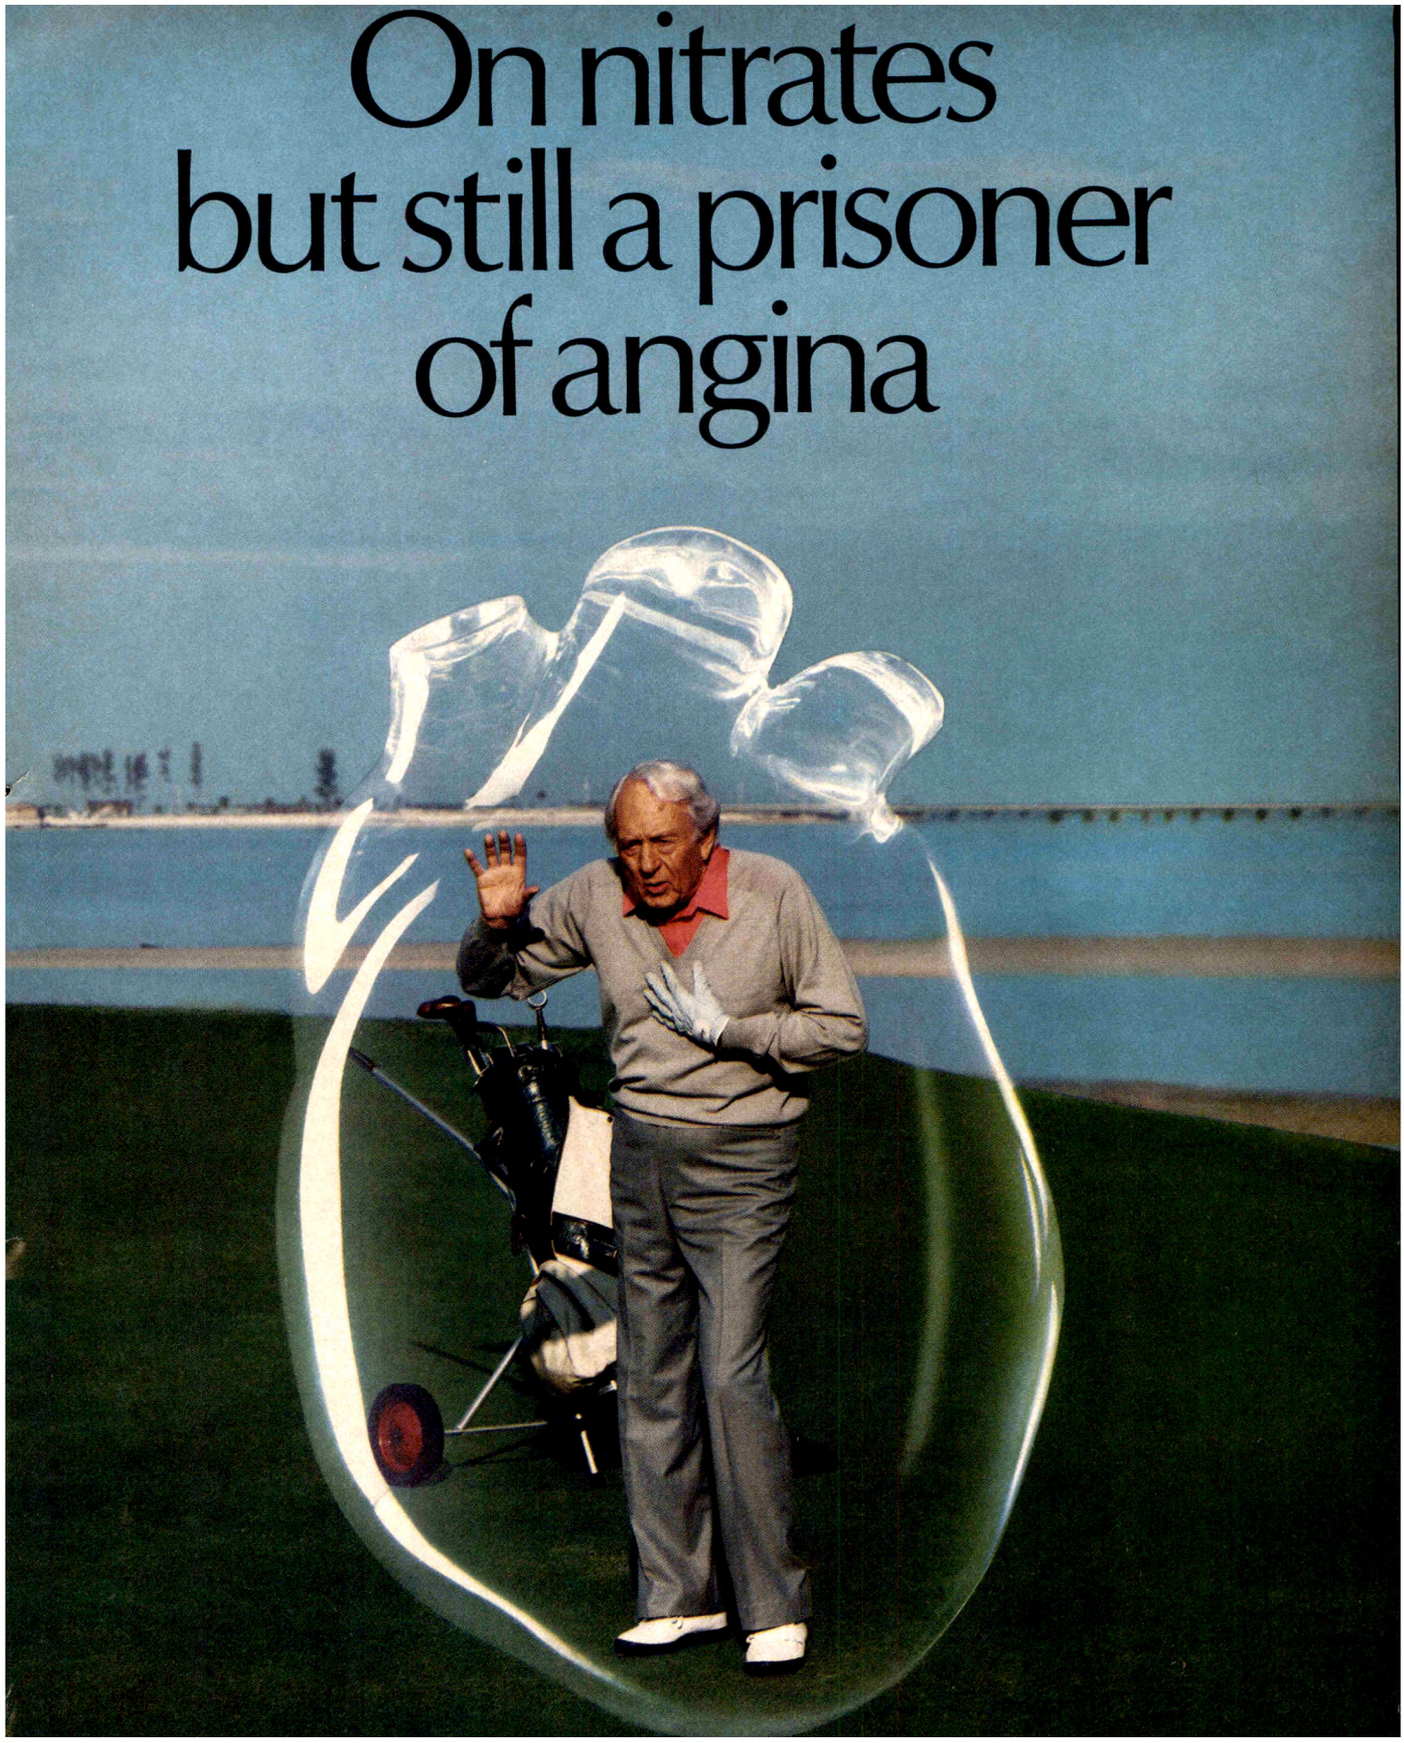
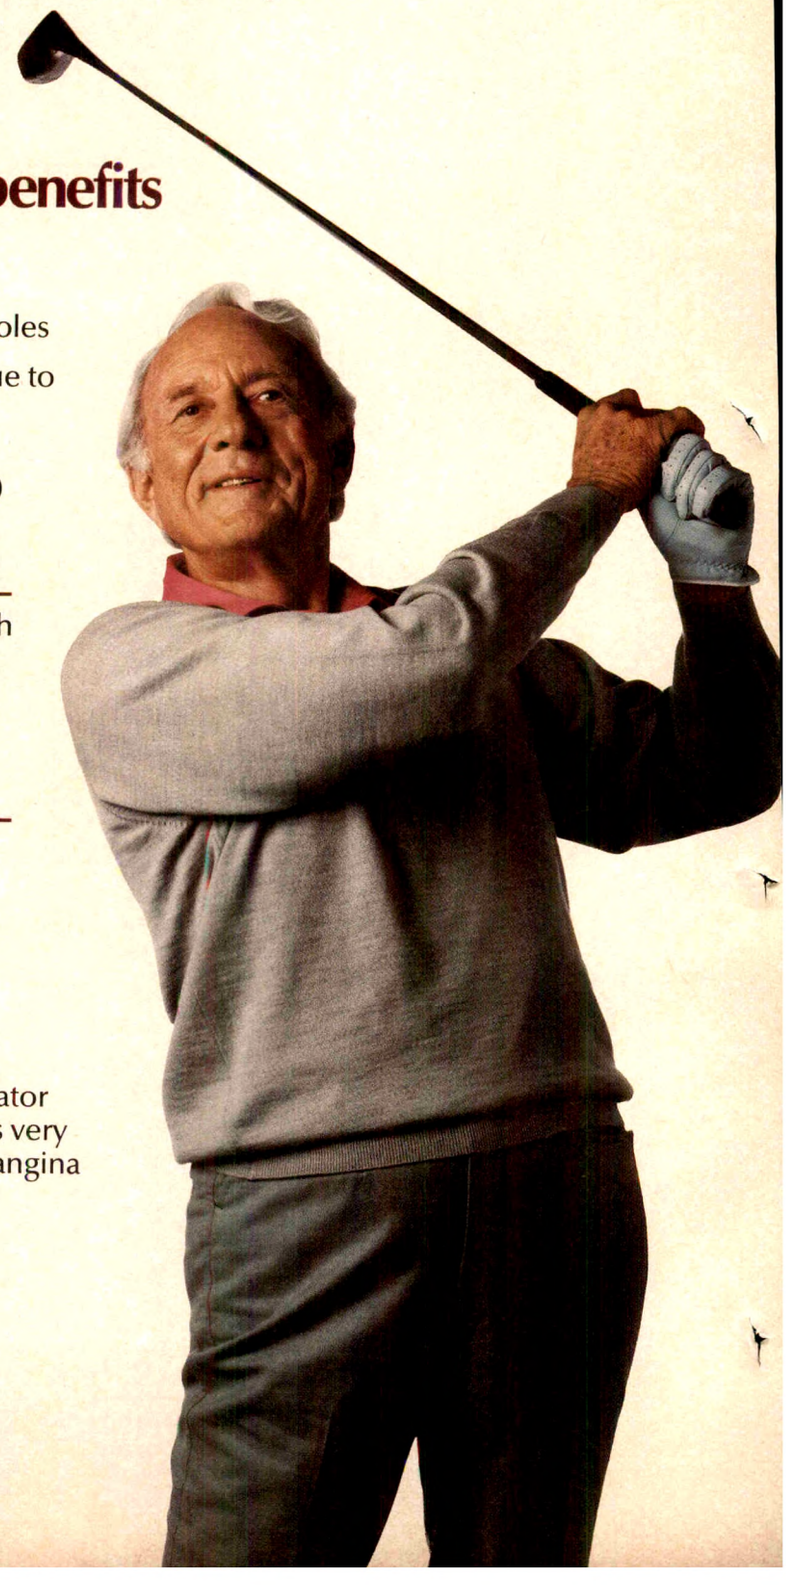
On nitrates but still a prisoner of angina



When nitrates alone are not enough

Add **Calan®** TABLETS
80 mg and 120 mg
(verapamil HCl)



Calan plus nitrates: Unique hemodynamic benefits

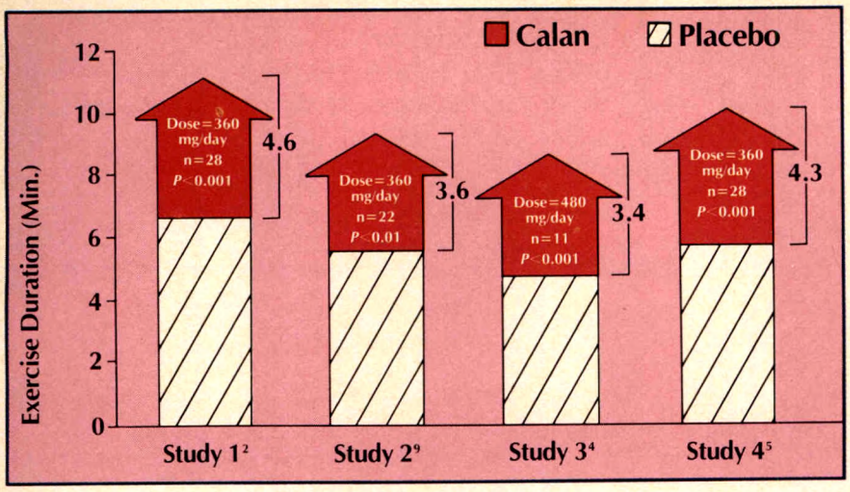
- increased myocardial oxygen supply—prevents vasoconstriction both in large coronary arteries and in coronary arterioles
- reduced myocardial oxygen demand due to
  - —a reduction in peripheral vascular resistance (afterload)
  - —a decrease in venous return (preload)
  - —a modest decrease in contractility

"It makes sense to treat those patients [with chronic stable angina]... [with] an agent that has a beneficial effect on both oxygen demand and supply, rather than a beta blocker which attacks just one side of that ratio."[1]

Calan plus nitrates: Efficacy for all types of angina

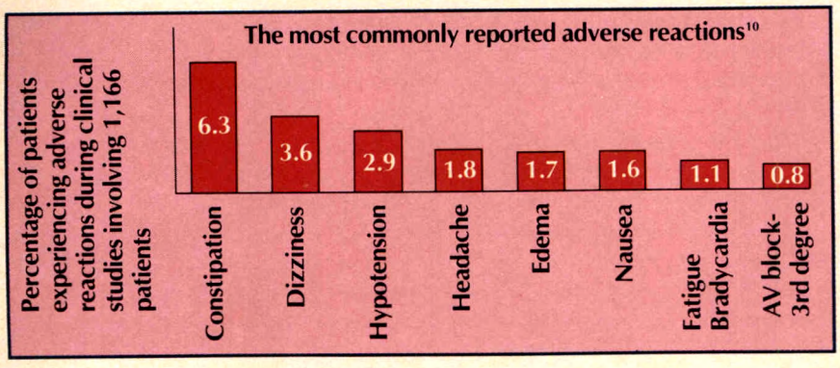
"...a combination of rate-lowering vasodilator (verapamil...) and long-acting nitrates...is very efficacious in patients with variant angina, angina of effort, and unstable angina at rest."[1]

Calan efficacy: Significant improvement in exercise tolerance[2-9]



- clinically significant improvement in exercise tolerance
- clinically significant reduction in the number of attacks and the need for sublingual nitroglycerin

Calan safety: Favorable side-effects profile



With Calan, side effects such as fatigue, mental depression, impotence or bradycardia (heart rate less than 50 beats/min) seldom occur.

In one study involving 63 patients "verapamil therapy was not discontinued in any patient because of the development of adverse reactions."[8]

Calan® *TABLETS*
80 mg and 120 mg
(verapamil HCl)

SEARLE

Please see following page for a brief summary of the complete prescribing information.

5W001T

Calan® TABLETS
80 mg and 120 mg
(verapamil HCl)

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block.

Warnings: Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension, usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Elevations of liver enzymes have been reported. Four cases have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually DC-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.

Precautions: Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Verapamil may decrease neuromuscular transmission in patients with Duchenne's muscular dystrophy and may prolong recovery from the neuromuscular blocking agent vecuronium. It may be necessary to decrease verapamil dosage in patients with attenuated neuromuscular transmission. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Concomitant use of inhalation anesthetics and calcium antagonists needs careful titration to avoid excessive cardiovascular depression. Verapamil may potentiate the activity of neuromuscular blocking agents (curare-like and depolarizing); dosage reduction may be required. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use.

Adverse Reactions: Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%); elevations of liver enzymes have been reported (see *Warnings*). The following reactions, reported in less than 0.5% of patients, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions, spotty menstruation, ecchymosis, bruising, gynecomastia, and psychotic symptoms. Overall continuation rate was 94.5% in 1,166 patients.

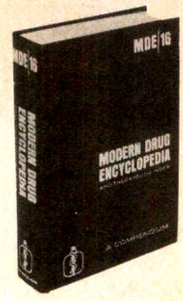
How thorough and unbiased is your drug reference?



If it's not the new 16th edition of MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Editor
Gertrude Dittus Gonzales, R.Ph., B.S., Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

THERE'S MORE THAN ONE WAY TO PHASE AN ARRAY

Now you can have more detailed depiction of cardiac anatomy...better tissue differentiation...improved visualization of septal borders and blood-filled chambers...intricate detail of valve leaflets...in images from the ULTRAMARK®8 Ultrasound System. Because we've created the ultimate phased array for cardiac imaging.

ATL's exclusive *annular phased array* with a small footprint scanhead incorporates the most desirable characteristics of both mechanical and traditional phased array technology while overcoming their limitations. It electronically phases and focuses a unique transducer with 5 concentric rings to produce the thinnest tomographic slice in imaging with unparalleled axial and lateral resolution.

The result: higher resolution images dynamically focused in two dimensions for visualization of structural detail in cardiac anatomy as you've never seen it before.

But don't take our word for it—see for yourself.

Call today to arrange for a demonstration—800-982-2011; in Washington, call collect: (206) 487-7067.

Transderm-Nitro®
nitroglycerin
Transdermal Therapeutic System

Brief Summary (For Full Prescribing Information, See Package Insert)

INDICATIONS AND USAGE
This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.
In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.
Transdermal nitroglycerin systems should be removed before attempting defibrillation or cardioversion because of the potential for altered electrical conductivity which may enhance the possibility of arcing, a phenomenon associated with the use of defibrillators.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.
Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.
Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.
The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response. The Transderm-Nitro 2.5 system is useful principally for decreasing the dosage gradually, though it may provide adequate therapy for some patients when used alone.
The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.
Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

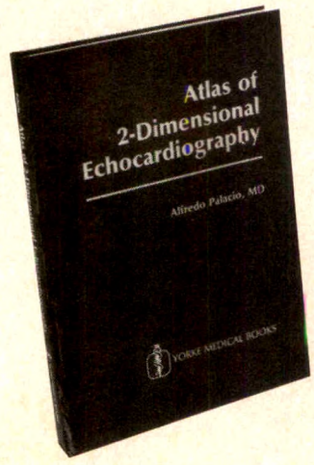
A "how-to-do-it" text/atlas presenting the broadest range of normal and abnormal 2-dimensional echocardiograms



Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School; Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts
ISBN 0-914316-35,4, 198pp., illus., large format 8¼ × 12, March '83, $69.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS of 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a large 8½ × 12 format 251 black and white half tones, 152 line drawings and 6 charts which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

Table of Contents

Foreword
Preface
Prologue
Introduction
EQUIPMENT
THE ECHOCARDIOGRAPHIC EXAMINATION
Parasternal position
Longitudinal plane
Transverse plane
Apical position
Hemiaxial plane
Axial plane
Subxiphoid position
Transvascular plane
Transcardiac plane
Suprasternal position
Longitudinal plane
Transverse plane
Final recommendations for the beginning technician
Special Controls
Compendium of tomographic sections
DISEASES
Mitral stenosis
Characteristics of the mitral stenosis in 2-dimensional echocardiography
Longitudinal plane, long axis of the left ventricle
Transverse plane, short axis
Direction of future investigations
Mitral regurgitation
Tricuspid valve
Aortic valve and aortic root
Pulmonary valve
Intracardiac masses and tumors
Pericardial effusion
Ischemic heart disease
Congenital heart disease
Cardiomyopathies
Systemic arterial hypertension
MISCELLANEOUS
Valvular prostheses
Performance and volume of the left ventricle
Intracavitary cables and catheters
Bibliographic references

All foreign orders must be prepaid in U.S. funds with a check drawn on a U.S. bank or charged to a credit card. Please add $5.00 per book for all orders to be shipped outside the U.S. and Canada.

"BIG SYSTEM" FEATURES AT A "LITTLE SYSTEM" PRICE

Quinton Q3000B Stress Test System

An affordable stress test system no longer means settling for second best. Not if your choice is Quinton's new Q3000B System—featuring our Q3000B Monitor and Corival 400 Ergometer.

Now the sophistication you require can be yours without the high price tag. Only Quinton Instrument Company offers you state-of-the-art stress test equipment with advanced features such as *ASVV, signal averaging, and programmability* at a "little system" price. That's not surprising—we were pioneers in the stress testing field, and we have worked very hard to provide only top quality equipment you know you can rely on. That's why we remain the world leader in stress systems.

The Q3000B may be just the system you need, particularly if you have limited work area available or if you are testing patients with physical limitations that preclude using treadmill testing.

- Some people, such as geriatric patients with low cardiopulmonary or muscular reserve, may be unable to walk or run on a treadmill.
- The initial workload can be set low on the bicycle ergometer and can be increased in small, precise increments.
- It is easier to identify and prescribe a precise, very low exercise program for physically impaired patients.
- The bicycle ergometer is often preferred for pediatric cardiology.
- The Q3000B System is less expensive and requires less floor space than an equivalent treadmill-based system.

Discover just how much your dollar can buy. We invite you to learn more about our stress test systems. Then compare and you will know why Quinton stress testing systems are unequalled when it comes to features and value. For more information, please contact:

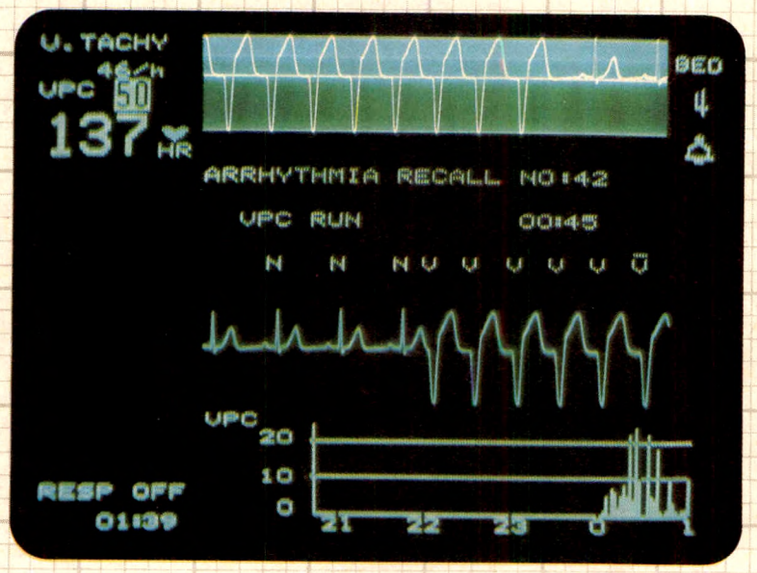
Lidocaine in the hospital.



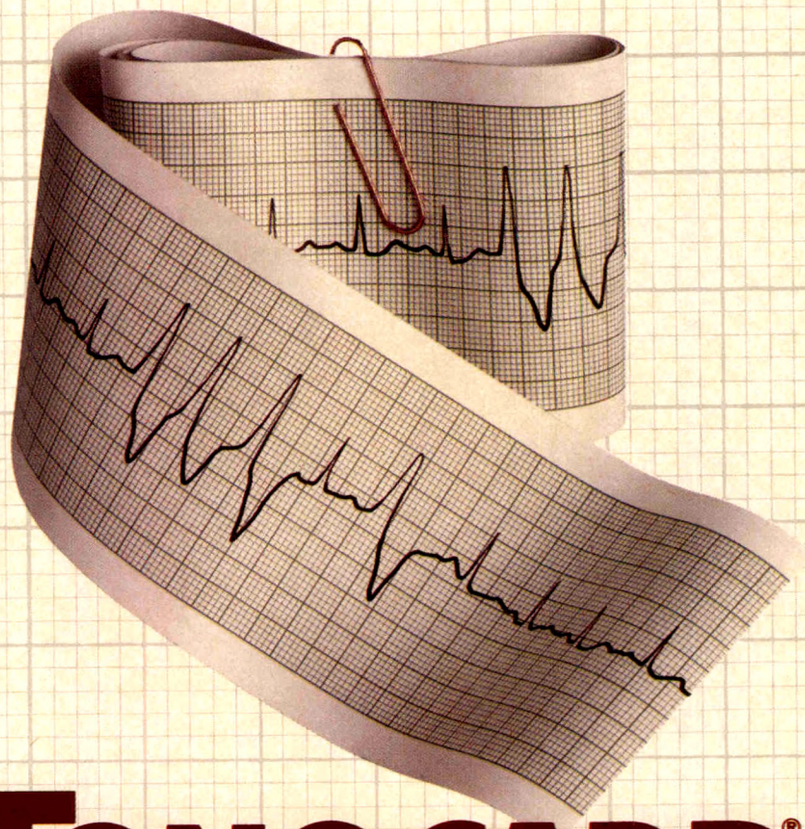
Like other antiarrhythmics, tocainide has not been shown to prevent sudden death, and also, like other antiarrhythmics, it has potentially serious adverse effects including the ability to worsen arrhythmias. Clinical and electrocardiographic evaluation should be used to periodically assess the need for therapy.

TONOCARD® (Tocainide HCl, MSD) is contraindicated in patients who are hypersensitive to this product or to local anesthetics of the amide type and in patients with second- or third-degree atrioventricular block in the absence of an artificial ventricular pacemaker.

Agranulocytosis, bone marrow depression, leukopenia, hypoplastic anemia, and thrombocytopenia have been reported in patients receiving TONOCARD; fatalities have occurred. Blood counts are recommended within the first two to three weeks of therapy and periodically thereafter. See Prescribing Information for details.

For a Brief Summary of Prescribing Information, please see last page of this advertisement.

TONOCARD in the office.



TONOCARD®
(TOCAINIDE HCl|MSD)

For symptomatic ventricular arrhythmias.

Like lidocaine. But it's oral.

TONOCARD
(TOCAINIDE HCl | MSD)

MSD
MERCK SHARP & DOHME

TONOCARD® (Tocainide HCl | MSD)

Like other antiarrhythmics, tocainide has not been shown to prevent sudden death in patients with serious ventricular ectopic activity, and also, like other antiarrhythmics, it has potentially serious adverse effects, including the ability to worsen arrhythmias. It is therefore essential that each patient given tocainide be evaluated electrocardiographically and clinically prior to, and during, tocainide therapy to determine whether the response to tocainide supports continued treatment.

CONTRAINDICATIONS

Patients who are hypersensitive to this product or to local anesthetics of the amide type.

Patients with second or third degree atrioventricular block in the absence of an artificial ventricular pacemaker.

WARNINGS

Blood Dyscrasias: Agranulocytosis, bone marrow depression, leukopenia, hypoplastic anemia and thrombocytopenia have been reported in patients receiving TONOCARD. Many of these events occurred in patients who were seriously ill and who were receiving concomitant drugs; fatalities have occurred. Since most of these events have been noted during the first 12 weeks of therapy, it is recommended that blood counts, including differential and platelet counts, be performed at least once within the first two to three weeks of therapy; and periodically thereafter, particularly within the first three months of therapy. Blood counts should be performed promptly if the patient develops any signs of infection (such as fever, chills, sore throat, or stomatitis), bruising, or bleeding. If any of these hematologic disorders is identified, TONOCARD should be discontinued and appropriate treatment should be instituted if necessary. Blood counts usually return to normal within one month of discontinuation. Caution should be used in patients with preexisting marrow failure or cytopenia of any type. (See ADVERSE REACTIONS).

Acceleration of Ventricular Rate: Acceleration of ventricular rate occurs infrequently when antiarrhythmics are administered to patients with atrial flutter or fibrillation (see ADVERSE REACTIONS).

PRECAUTIONS

General

Pulmonary Fibrosis: Pulmonary fibrosis, interstitial pneumonitis, fibrosing alveolitis, pulmonary edema, and pneumonia, possibly drug related, have been reported in patients receiving TONOCARD. Many of these events occurred in patients who were seriously ill. The experiences are usually characterized by bilateral infiltrates on x-ray and are frequently associated with dyspnea and cough. Fever may or may not be present. Patients should be instructed to promptly report the development of any pulmonary symptoms such as exertional dyspnea, cough or wheezing. Chest x-rays are advisable at that time. If these pulmonary disorders develop, TONOCARD should be discontinued. (See ADVERSE REACTIONS).

In patients with known heart failure or minimal cardiac reserve, TONOCARD should be used with caution because of the potential for aggravating the degree of heart failure.

Caution should be used in the institution or continuation of antiarrhythmic therapy in the presence of signs of increasing depression of cardiac conductivity.

In patients with severe liver or kidney disease, the rate of drug elimination may be significantly decreased (see DOSAGE AND ADMINISTRATION).

Since antiarrhythmic drugs may be ineffective in patients with hypokalemia, the possibility of a potassium deficit should be explored and, if present, the deficit should be corrected.

Like all other oral antiarrhythmics, TONOCARD has been reported to increase arrhythmias in some patients (see ADVERSE REACTIONS).

Information for Patients

Patients should be instructed to promptly report the development of bruising or bleeding; any signs of infections such as fever, chills, sore throat, or soreness and ulcers in the mouth; or any pulmonary symptoms, such as exertional dyspnea, cough, or wheezing.

Laboratory Tests

As with other antiarrhythmics, abnormal liver function tests, particularly in the early stages of therapy, have been reported. Periodic monitoring of liver function should be considered. Hepatitis and jaundice have been reported in some patients.

Drug Interactions

Specific interaction studies with digoxin and metoprolol have been conducted, no clinically significant interaction was seen with digoxin, but tocainide and metaprolol had additive effects on wedge pressure and cardiac index. TONOCARD has also been used in open studies with digitalis, beta-blocking agents, other antiarrhythmic agents, anticoagulants, and diuretics, without evidence of clinically significant interactions. Nevertheless, caution should be exercised in the use of multiple drug therapy.

TONOCARD is equally effective in digitalized and non-digitalized patients. In 17 patients with refractory ventricular arrhythmias on concomitant therapy, serum digoxin levels (1.1 ± 0.4 ng/mL) remained in the expected normal range (0.5-2.5 ng/mL) during tocainide administration.

Pregnancy

Pregnancy Category C. In a teratogenicity study in rabbits, tocainide was administered orally at doses of 25, 50, and 100 mg/kg/day (about 1 to 4 times the usual human dose). No evidence of a drug-related teratogenic effect was noted; however, these doses were maternotoxic and produced a dose-related increase in abortions and stillbirths. In a teratogenicity study in rats, an oral dose of 300 mg/kg/day (about 12 times the usual human dose) showed no evidence of treatment-related fetal malformations, but maternotoxicity and an increase in fetal resorptions were noted. An oral dose of 30 mg/kg/day (about twice the usual human dose) did not produce any adverse effects.

In reproduction studies in rats at maternotoxic oral doses of 200 and 300 mg/kg/day (about 8 and 12 times the usual human dose, respectively), dystocia, and delayed parturition occurred which was accompanied by an increase in stillbirths and decreased survival in offspring during the first week postpartum. Growth and viability of surviving offspring were not affected for the remainder of the lactation period.

There are no adequate and well-controlled studies in pregnant women. TONOCARD should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers

It is not known whether tocainide is secreted in human milk. Because many drugs are secreted in human milk and because of the potential for serious adverse reactions in nursing infants from TONOCARD, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use

Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

TONOCARD commonly produces minor, transient, nervous system and gastrointestinal adverse reactions, but is otherwise generally well tolerated. TONOCARD has been evaluated in both short-term (n = 1,358) and long-term (n = 262) controlled studies as well as a compassionate use program. Dosages were lower in most of the controlled studies (1200 mg/day) and higher in the compassionate use program (1800 mg and more). In long-term (2-6 months) controlled studies, the most frequent adverse reactions were lightheadedness/dizziness (15.3 percent), nausea (14.5 percent), paresthesia/numbness (9.2 percent), and tremor (8.4 percent). These reactions were generally mild, transient, dose-related and reversible with a reduction in dosage, by taking the drug with food, or by therapy discontinuation. Tremor, when present, may be useful as a clinical indicator that the maximum dose is being approached. Adverse reactions leading to therapy discontinuation occurred in 21 percent of patients in long-term controlled trials and were usually related to the nervous system or gastrointestinal system.

Adverse reactions occurring in greater than one percent of patients from the short-term and long-term controlled studies appear in the following table:

	Percent of Patients Controlled Studies	
	Short-term (n = 1,358)	Long-term (n = 262)
NERVOUS SYSTEM		
Lightheadedness/dizziness/vertigo/giddiness	8.0	15.3
Parasthesia/numbness	3.5	9.2
Tremor/quivering/tremulousness	2.9	8.4
Confusion/disorientation/hallucinations	2.1	2.7
Altered mood/awareness	1.5	3.4
Restlessness/shakiness/nervousness	1.5	0.4
Blurred vision/visual disturbances	1.3	1.5
Discoordination/unsteadiness/walking disturbances	1.2	0.0
Anxiety	1.1	1.5
Tinnitus/hearing loss	0.4	1.5
Ataxia	0.2	3.0
Nystagmus	0.0	1.1
GASTROINTESTINAL SYSTEM		
Nausea	15.2	14.5
Vomiting	8.3	4.6
Anorexia	1.2	1.9
Diarrhea/loose stools	0.0	3.8
CARDIOVASCULAR SYSTEM		
Hypotension	3.4	2.7
Bradycardia	1.8	0.4
Palpitations	1.8	0.4
Chest Pain	1.6	0.4
Conduction disturbances	1.5	0.0
Left ventricular failure	1.4	0.0
OTHER		
Sweating/cold sweat/night sweats/clammy	5.1	2.3
Headache	2.1	4.6
Tiredness/drowsiness/fatigue/lethargy/lassitude/sleepiness	1.6	0.8
Hot/cold feelings	0.5	1.5
Rash/skin lesion	0.4	8.4

An additional group of about 2,000 patients has been treated in a program allowing for the use of TONOCARD under compassionate use circumstances. These patients were seriously ill with the large majority on multiple drug therapy, and comparatively high doses of TONOCARD were used. Fifty-four percent of the patients continued in the program for one year or longer, and 12 percent were treated for longer than three years, with the longest duration of therapy being nine years. Adverse reactions leading to therapy discontinuation occurred in 12 percent of patients (usually central nervous system effects or rash). A tabulation of adverse reactions occurring in one percent or more of patients follows:

	Percent of Patients Compassionate Use (n = 1,927)
NERVOUS SYSTEM	
Lightheadedness/dizziness/vertigo/giddiness	25.3
Tremor/quivering/tremulousness	21.6
Restlessness/shakiness/nervousness	11.5
Confusion/disorientation/hallucinations	11.2
Altered mood/awareness	11.0
Ataxia	10.8
Blurred vision/visual disturbances	10.0
Paresthesia/numbness	9.2
Nystagmus	1.1
GASTROINTESTINAL SYSTEM	
Nausea	24.6
Anorexia	11.3
Vomiting	9.0
Diarrhea/loose stools	6.8
CARDIOVASCULAR SYSTEM	
Increased ventricular arrhythmias/PVCs	10.9
CHF/progression of CHF	4.0
Tachycardia	3.2
Hypotension	1.8
Conduction disturbances	1.3
Bradycardia	1.0
OTHER	
Rash/skin lesion	12.2
Sweating/cold sweat/night sweats/clammy	8.3
Arthritis/arthralgia	4.7
Myalgia	1.7
Lupus	1.6

Adverse reactions occurring in less than one percent of patients in either the controlled studies or the compassionate use program or since the drug was marketed are as follows:

Nervous System: Coma, convulsions/seizures, depression, psychosis, mental change, agitation, altered taste/smell, difficulty concentrating, diplopia, dysarthria, impaired memory, increased stuttering/slurred speech, insomia/sleeping disturbance, local anesthesia, nightmares, thirst, weakness, myasthenia gravis.

Gastrointestinal System: Abnormal liver function tests, hepatitis, jaundice, (see PRECAUTIONS); stomatitis; abdominal pain/discomfort; constipation; dysphagia; gastrointestinal symptoms (including dyspepsia).

Cardiovascular System: Ventricular fibrillation, extension of acute myocardial infarction, cardiogenic shock, angina, AV block, hypertension, increased QRS duration, pleurisy/pericarditis, prolonged QT interval, right bundle branch block, syncope, vasovagal episodes, cardiomegaly, sinus arrest.

Pulmonary System: Respiratory arrest, pulmonary edema, pulmonary embolism, pulmonary fibrosis, fibrosing alveolitis, interstitial pneumonitis, pneumonia, dyspnea.

Other: Hematologic disorder (agranulocytosis, bone marrow depression, hypoplastic anemia, anemia, leukopenia, thrombocytopenia), increased ANA, urinary retention, polyuria/increased diuresis, alopecia, cinchonism, claudication, cold extremities, dry mouth, earache, edema, fever, hiccups, itching, leg cramps, malaise, metallic/menthol taste, muscle twitching/spasm, neck pain, pain radiating from neck, pallor/flushed face, pressure on shoulder, yawning.

Agranulocytosis, bone marrow depression, leukopenia, hypoplastic anemia, and thrombocytopenia have been reported (0.18 percent) in patients receiving TONOCARD in controlled trials and the compassionate use program. Many of these events occurred in patients who were seriously ill or who were receiving concomitant drugs; fatalities have occurred. Most of these events have been noted during the first 12 weeks of therapy. (See WARNINGS).

Pulmonary fibrosis, interstitial pneumonitis, fibrosing alveolitis, pulmonary edema, and pneumonia, possibly drug related, have been reported in patients receiving TONOCARD. The incidence of pulmonary fibrosis (including interstitial pneumonitis and fibrosing alveolitis) was 0.11 percent in controlled trials and the compassionate use program. These events usually occurred in seriously ill patients. Symptoms of these pulmonary disorders and/or x-ray changes usually occurred following 3-18 weeks of therapy and two patients died. (See PRECAUTIONS).

HOW SUPPLIED

Tablets containing 400 mg (scored) or 600 mg in bottles of 100 and unit-dose packages of 100.

For more detailed information consult your MSD Representative and the Prescribing Information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, PA 19486.

CORONARY HEART DISEASE

Effect of Intracoronary Thrombolytic Therapy on Exercise-Induced Ischemia After Acute Myocardial Infarction

JACQUES A. MELIN, MD, PATRICK M. DE COSTER, MD, JEAN RENKIN, MD, JEAN-MARIE R. DETRY, MD, CHRISTIAN BECKERS, MD, and JACQUES COL, MD

Intracoronary streptokinase (SK) therapy increases vessel patency rate after acute myocardial infarction (AMI) and thus may lead to a greater exercise-induced myocardial ischemia. This hypothesis was tested in 39 patients enrolled in an angiographically randomized trial of intracoronary SK (19 treated with SK and 20 control subjects); all patients underwent thallium-201 scintigraphy at rest before acute angiography, as well as at rest and during stress 5 to 6 weeks after AMI. The patients were classified into 2 groups based on the presence (n = 13) or absence (n = 26) of complete obstruction of the infarct-related coronary artery at the end of the acute angiography. Semiquantitative score of myocardial thallium uptake was expressed as percent of maximal defect score. Thallium defect score at rest between admission and 5 to 6 weeks' study decreased from 10 ± 16% units in the control group and from 23 ± 14% units in the SK group (p = 0.01). This decrease was related to opening of the infarct-related artery (opening 23 ± 16% vs occlusion 5 ± 10%). The change in exercise-induced defect score was significantly (p = 0.01) larger in patients in the SK group (11 ± 6% units) than in those in the control group (5 ± 7% units). The perfusion defect during exercise was larger (p = 0.006) in patients with incomplete obstruction or reperfusion (10 ± 6% units) than in patients with complete obstruction (3 ± 7%). This difference was independent of the number of diseased coronary vessels. Radionuclide ventriculography during submaximal exercise was performed within 2 to 3 weeks after AMI in 21 of the 39 patients studied. The exercise-induced increase in ejection fraction was significantly smaller in patients with opened vessels (4 ± 7%) than in those with closed vessels (13 ± 9%; p = 0.03). Thus, in this group of patients who were studied 5 to 6 weeks after AMI, patients treated with SK demonstrated scintigraphic improvement at rest compared with results at admission, but had more exercise-induced ischemia; this was related to incomplete coronary obstruction or reperfusion.

(Am J Cardiol 1985;56:705–711)

From the Division of Intensive Care, the Center of Nuclear Medicine and the Division of Cardiology, University of Louvain Medical School, Brussels, Belgium. This study was supported in part by Grants 3.4537.83 and 3.4536.83 from the Fonds de la Recherche Scientifique Médicale and Grant 83/8851 from the Services de Programmation de la Politique Scientifique, Belgium. Manuscript received April 8, 1985; revised manuscript received June 3, 1985, accepted June 6, 1985.

Address for reprints: Jacques A. Melin, MD, Centre de Médecine Nucléaire, UCL 54.30, Avenue Hippocrate, 54, B-1200 Brussels, Belgium.

In patients with evolving acute myocardial infarction (AMI), successful reperfusion can be achieved after thrombolysis with intracoronary streptokinase (SK).[1–4] However, residual high-grade stenoses frequently remain at the site of initial occlusion and may result in rethrombosis.[5,6] Furthermore, these residual stenoses may predispose the patient to persistent angina pectoris

or exercise-induced ischemia. We studied this latter possibility in patients enrolled in a randomized, angiographically controlled trial of intracoronary SK therapy. The patients studied were selected because they had undergone admission thallium scintigraphy and underwent scintigraphy at rest and during exercise 5 to 6 weeks after AMI. In this subset of patients, we analyzed the changes in perfusion scans at rest between admission and 5 to 6 weeks after AMI and compared these data with the exercise scintigrams obtained 5 to 6 weeks after AMI.

Methods

All patients included in a randomized trial of intracoronary SK between October 1981 and August 1984 were considered for the study. However, only those who underwent thallium scintigraphy at rest and during exercise 5 to 6 weeks after AMI were included in the present study. The protocol of the randomized trial has been described.[7] Eighty-three patients who presented to the hospital within 3 hours of the onset of chest pain were enrolled in the trial (41 in the control group and 42 in the SK group). The patients were retrospectively classified into 2 subgroups based on the angiographic absence or presence of complete obstruction of the infarct-related coronary artery. Three patients died in cardiogenic shock during the first 12 hours after admission. Three other patients died during the 2-month follow-up period. The 6 patients who died had a complete coronary artery obstruction (3 in the control group and 3 in the SK group). During the first 5 weeks after AMI, 1 patient (treated with SK) had a reinfarction and 4 patients underwent coronary artery bypass surgery (2 treated with SK and 2 control subjects). Six patients in the SK group and 2 in the control group underwent coronary balloon dilation. In the 12 patients who underwent surgical or angioplasty treatment, the infarct-related coronary artery was found to be patent. From the remaining 64 patients (34 in the control group and 30 in the SK group), 25 patients (14 control subjects and 11 treated with SK) did not undergo exercise testing combined with thallium imaging 5 to 6 weeks after AMI. Among these 25 patients, 6 (2 control subjects and 4 treated with SK) had typical symptoms of angina pectoris or positive electrocardiographic findings during exercise. These 6 patients had a patent infarct-related coronary artery.

The present study group comprised 39 patients (33 men, 6 women), aged 37 to 70 years (mean 55 ± 19). Two patients (1 treated with SK and 1 control subject) had a history of AMI. Diagnosis of AMI was based on typical prolonged chest pain at rest, lasting for more than 30 minutes and persistent ST-segment elevation of at least 2 mm in 3 or more leads of the standard 12-lead electrocardiogram. The final diagnosis of AMI was retrospectively confirmed from serial serum creatine kinase values. As soon as possible after the admission and inclusion in the randomized trial, 1.5 mCi of thallium-201 were intravenously injected. Ten minutes after injection of thallium-201, intravenous infusion of nitroglycerin was begun. Immediately after the initiation of nitrate therapy, thallium-201 imaging was begun and the acquisition of the 3 standard views was made within 30 minutes. Without taking into account the results of thallium-201 scintigraphy, patients were randomly assigned to a control group (n = 20) and an SK group (n = 19). After 10,000 units of intravenous heparin had been administered, coronary angiography was performed. The interval from the onset of infarct symptoms to angiography was 266 ± 152 minutes in the control group and 234 ± 50 minutes in the SK group. Nitroglycerin (500 μg) was injected into the coronary artery to exclude a coronary spasm. In the SK group, SK was infused into the coronary artery at a mean dose of 240,526 ± 45,761 IU within 45 minutes. Coronary angiography was repeated at the end of SK infusion to evaluate the success of recanalization and the residual stenosis at the site of occlusion. Intravenous heparin infusion (20,000 IU/day) was given for the first 2 days after catheterization. Oral nitrates were routinely given after withdrawal of intravenous infusion (2 to 4 days after beginning of infusion). All patients subsequently received antiplatelet agents (aspirin and dipyridamole) and calcium antagonist drugs.

Exercise protocols: All patients underwent maximal exercise combined with thallium-201 imaging 5 to 6 weeks after AMI. Twenty-one of the 39 patients also underwent radionuclide ventriculography during submaximal exercise 2 to 3 weeks after AMI.

Thallium scintigraphy during maximal exercise: The exercise tests were performed on a bicycle ergometer with an initial workload of 20 W; the exercise intensity was increased by 20 W every minute until the patient had typical anginal pain or until subjective exhaustion. Three Frank orthogonal leads were constantly monitored and recorded on paper every minute during exercise and the first 5 minutes of the recovery. A 20-second electrocardiographic sample was also recorded on a digital magnetic tape at the end of every minute, at rest, during the exercise and during the recovery. These digitized electrocardiographic samples were averaged and analyzed by computer (Modcomp 11/25) using an adapted version of the program of the Thoraxcenter in Rotterdam.[8] The amount of ST-segment depression during maximal exercise was measured 80 ms after the end of QRS with the PR interval as reference level. A positive electrocardiographic response during exercise was defined as horizontal ST depression equal to or greater than 0.1 mV.

The technique for myocardial perfusion imaging has been described.[9] During the same testing session in which the exercise electrocardiogram was performed, thallium-201 (1.5 to 2 mCi) was injected intravenously, 1 minute before maximal exercise. Images (250,000 counts) were obtained in the anterior, left anterior oblique 45° and 65° positions. A separate thallium study at rest was performed 2 to 4 days after the exercise study. The 3 thallium studies (preintervention, 6-week rest and stress) were independently interpreted without computer processing by 2 observers who had no knowledge of the clinical, angiographic or electrocardiographic findings. Each view was separated into 5 segments, yielding a total of 15 segments. The thallium uptake in each segment was classified as: 0 = normal; 1 = possibly reduced; 2 = reduced; and 3 = absent. The maximal defect score 45 originates from 15 segments times a maximal score of 3. The data are presented as the percentage of a maximal defect score (equal to 45 or 100%) that would be obtained if no thallium uptake was shown on the 3 views.

Radionuclide ventriculography during submaximal exercise: Twenty-one patients underwent semisupine bicycle exercise testing with radionuclide ventriculography 17 ± 6 days after AMI while taking their usual medications. The Frank lead system was used for continuous monitoring of the electrocardiographic response to exercise. Exercise commenced at 200 kpm/min and increased by 200 kpm/min at each subsequent exercise level. The patients exercised for 5 minutes at incremental workloads until 1 of the following endpoints was reached: (1) a heart rate of 120 beats/min; (2) complex ventricular arrhythmias; (3) angina pectoris; (4) a decrease in blood pressure during exercise; and (5) exhaustion or dyspnea. Multigated equilibrium blood pool imaging was performed using an in vivo technique of labeling red blood cells with 20 mCi of technetium-99m sodium pertechnetate. Data acquisition was performed in a modified 30° to 60° left anterior oblique view with a 10° caudal tilt adjusted to provide the best definition of the interventricular septum. All images

were acquired using a Elscint Apex-215M gamma camera. Twenty-four synchronized images were acquired in 64 by 64 byte mode for 3 minutes. Data acquisition was begun at each workload after the completion of 2 minutes of exercise, which allowed the heart rate to stabilize. Left ventricular ejection fraction was calculated after determination of background-corrected left ventricular time-activity curve. For each frame in the cardiac cycle, activity within the region of the left ventricle was determined using a second-derivative edge-detection algorithm

Coronary angiography: Angiographic patency was considered present if the infarct-related artery showed a good runoff of contrast material. The interpretation was made by an angiographer unaware of the results of the thallium scintigram. In the SK group, it was defined from the coronary angiogram performed immediately after SK infusion. Within the 6 weeks after AMI a follow-up angiogram was performed in 29 patients (24 of 26 patients who underwent successful reperfusion and in 5 of 13 patients who did not). Multivessel disease was defined as 70% or more narrowing of luminal diameter of at least 2 of the 3 major coronary arteries (left anterior descending, left circumflex and right). Stenosis was measured by calipers in 2 oblique projections.

Statistical analysis: Data are expressed as mean ± standard deviation. Comparison of data between groups was made by unpaired *t* test. A 2-way analysis of variance was performed with 2 grouping factors (coronary patency and number of diseased vessels). The p values presented for this analysis are from tests on the main effects of these 2 factors whereas the interaction was not significant.

Results

Coronary angiography: The 39 patients were retrospectively separated into 2 groups based on the presence or absence of complete obstruction of the infarct-related coronary artery. Baseline angiography revealed that the infarct-related coronary artery was completely obstructed in 18 of 19 patients (95%) receiving SK and in 14 of 20 patients (70%) in the control group. Recanalization of complete coronary artery obstruction occurred in 16 of 18 patients in the SK group and in 3 of 14 patients in the control group. Thus, post-intervention angiography revealed patency of the infarct-related coronary artery in 26 of 39 patients (67%). An anterior infarct was present in 13 of these 26 patients (50%) and in 7 of 13 patients (54%) with coronary obstruction. Twenty of these 26 patients had greater than 70% luminal stenosis of the artery; 5 patients had a 50 to 70% stenosis and 1 patient had a 30% residual stenosis. Follow-up angiography available in 24 of these 26 patients revealed reocclusion in 2 patients with greater than 90% luminal stenosis (2 of 24 [8%]). In 7 of these 24 patients, there was a substantial decrease (10 to 30%) in the remaining stenosis of the infarct-related coronary artery on the follow-up angiogram compared with the acute angiography. These 7 patients had greater than 70% stenosis that decreased to a 50 to 70% stenosis. Twenty-two patients had 1-vessel and 17 patients had multivessel disease, including 10 with 2-vessel and 7 with 3-vessel coronary disease (and no left main coronary artery stenosis).

Enzyme kinetics data: Peak creatine kinase values were lower in patients with incomplete coronary obstruction (1,377 ± 1,087 IU) than in those with complete obstruction recanalized (3,176 ± 1,123 IU) or not recanalized (2,184 ± 1,386 IU). The time required to reach the peak creatine kinase value did not differ significantly between patients with incomplete coronary obstruction on the baseline angiogram (15 ± 4 hours) and those in whom complete obstruction was recanalized (14 ± 6 hours). In both groups the creatine kinase value peaked earlier than in patients in whom complete coronary obstruction was not recanalized (23 ± 5 hours).

Thallium-201 scintigraphy at rest: Thallium-201 defect scores were compared for the preintervention and the 5 to 6 weeks' follow-up studies (Table I and Fig. 1).

Defect score decreased by 10 ± 16% units in the control group and by 23 ± 14% units in the SK group (p = 0.01). The decrease was related to opening of the infarct-related artery (23 ± 16% units in the patients with opened vessel vs 5 ± 10% units in those with closed vessel, p = 0.001).

Thallium-201 scintigraphy during maximal exercise: The results of exercise thallium-201 scintigraphy are listed in Table I. Only 2 patients had chest pain during exercise (the first with patent infarct-related artery and 1-vessel disease; the second with complete obstruction and 3-vessel disease). Positive electrocardiographic findings during exercise were found in 8 patients (42%) treated with SK (6 with 1-vessel disease) and in 13 (50%) with opened infarct-related vessel (7 with 1-vessel disease). The individual changes in thallium-201 defect scores during maximal exercise are shown in Figure 2. The magnitude of thallium defect score reflecting ischemia (exercise-induced score change) was significantly (p = 0.01) larger in patients in the SK group (11 ± 6% units) than in patients in the control group (5 ± 7% units). The exercise-induced defect score was found to be significantly associated with opening of the infarct-related vessel; in the patients with opened vessel, the exercise-induced defect score was 10 ± 6 vs 3 ± 7% units in the patients with closed vessel (p = 0.006). As shown in Table II, this difference was independent of the number of diseased coronary vessels (2-way analysis of variance).

Radionuclide ventriculography during submaximal exercise: Table III and Figure 3 illustrate the magnitude of change in ejection fraction from rest to submaximal exercise in 21 of 39 patients. Comparison of the admission (postintervention) contrast ejection

fraction and the predischarge radionuclide ejection fraction showed no significant differences between the patients treated with SK (52 ± 12 and 45 ± 15%; difference not significant [NS]) and the control subjects (51 ± 12 and 46 ± 16%; NS). The patients with obstructed artery had an initial ejection fraction of 52 ± 13% and a predischarge ejection fraction of 47 ± 16% (NS). The ejection fraction in patients with incomplete obstruction or reperfused artery was initially 50 ± 11% and at follow-up 45 ± 16%. The 2 groups did not differ significantly with regard to initial or interval change in ejection fraction. The exercise-induced increase in left ventricular ejection fraction was significantly higher in patients with complete coronary obstruction ($p = 0.03$). Among the patients with 1-vessel disease ($n = 13$), the increase in ejection fraction during exercise was also higher in patients with closed infarct-related artery (12 ± 9% units) than in those with opened artery (5 ± 9% units). In the same subgroup of 21 patients, the magnitude of thallium defects reflecting exercise ischemia (change between study at rest and during exercise) was higher in the patients treated with SK ($p = 0.03$) than in the control group, and higher in patients with patent infarct-related artery ($p = 0.07$) than in patients with closed vessel.

Discussion

Five to 6 weeks after AMI, patients treated with SK had improvement in their perfusion scintigrams at rest compared with those at admission, but had more exercise-induced ischemia. In this randomized, angiographically controlled trial of intracoronary SK therapy, the reduction in thallium perfusion defect at rest and the subsequent exercise-induced ischemia occurred in those patients with subtotal occlusion of the infarct-related artery or with successful reperfusion, both in those treated with SK and in the control group.

In this trial, the patients were retrospectively classified on the basis of the angiographic demonstration of patency or total obstruction of the infarct-related artery. Analysis of creatine kinase curves lent further support to the angiographic data; an early peaking of creatine kinase values was found both in patients with catheterization reperfusion and in those with incomplete coronary obstruction on the baseline angiogram. Our population included only the 39 patients who underwent exercise thallium scintigraphy 5 to 6 weeks after AMI. All patients were asymptomatic besides 2 who had angina during exercise. In the remaining 44 patients enrolled in the trial, recurrent coronary events occurred in 19 patients: 1 patient had a reinfarction, 12 underwent coronary balloon angioplasty or bypass surgery and 6 had angina pectoris or abnormal exercise electrocardiographic findings. Those 19 patients represent 70% of those who demonstrated incomplete coronary obstruction or successful reperfusion at the end of admission angiography.

The present study addresses the clinical issue of the residual high-grade stenoses after spontaneous or fibrinolytic reperfusion. Reocclusion has been reported in less than 10 to 32% of patients undergoing follow-up angiography after thrombolysis.[1,2,5,10,11] Of the 26 patients with patent infarct-related coronary artery in the present study, 8% showed reocclusion at the follow-up angiography. Besides the risk of rethrombosis, another potential issue of residual stenosis is exercise-induced ischemia. Previous studies have focused on recurrent angina. In the Western Washington randomized trial, the group treated with SK had less severe angina at the time of hospital discharge than did the control group.[12] In another randomized trial, angina occurred in more control than SK patients during the 19-month follow-up.[13] In a third randomized trial,[14] patients were classified according to the absence or presence of reperfusion after treatment; the incidence of postinfarction angina was similar in the group in whom reperfusion was achieved (21%) and in the group in whom it was not (35%).

In the present study, most patients who underwent thallium scintigraphy during exercise 5 to 6 weeks after

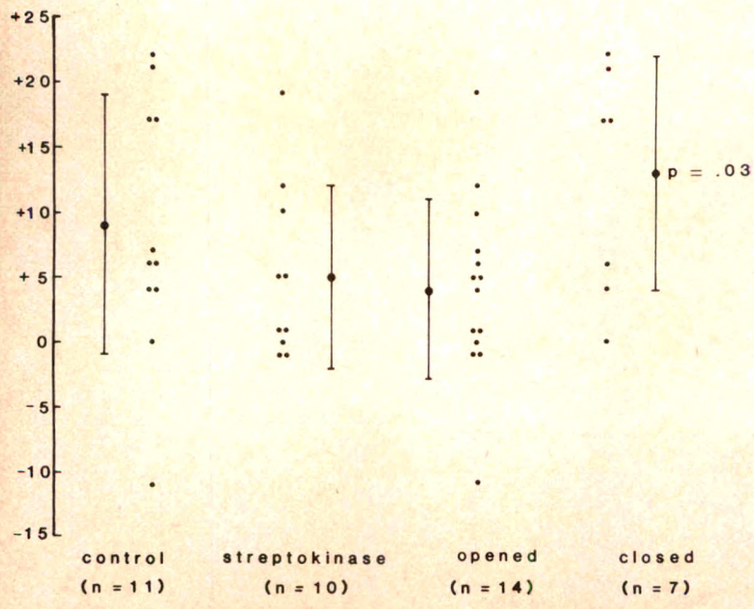

FIGURE 3. Individual changes in radionuclide left ventricular ejection fraction during submaximal exercise.

AMI were asymptomatic. In this group, the presence of an exercise-induced perfusion defect was related to a persistent coronary stenosis. Furthermore, in a subgroup of these patients, radionuclide angiography during submaximal exercise showed that the increase in ejection fraction was significantly greater in patients with closed infarct-related artery (13%) than in those with patent artery (4%). The clinical implications of these findings for the routine management of patients undergoing fibrinolysis after AMI remain to be elucidated. The optimal management course after successful thrombolytic therapy has not been defined. Both percutaneous transluminal coronary angioplasty[15–20] and coronary artery bypass grafting[21–23] have been advocated to prevent reocclusion and recurrent ischemic events. As emphasized by Laffel and Braunwald,[24] these treatments might be indicated after thrombolytic therapy if the patient has angina despite intensive medical therapy or demonstrates persistent myocardial ischemia, particularly in the myocardium perfused by the artery in which thrombolysis has occurred.

Primary Angiographic Success Rates of Percutaneous Transluminal Coronary Angioplasty

H. VERNON ANDERSON, MD, GARY S. ROUBIN, MB, PhD, PIERRE P. LEIMGRUBER, MD, JOHN S. DOUGLAS, Jr., MD, SPENCER B. KING, III, MD, and ANDREAS R. GRUENTZIG, MD

Three distinct periods in catheter design have been identified since the advent of percutaneous transluminal coronary angioplasty (PTCA) in 1977. In the first period PTCA was performed using a double-lumen balloon catheter that had a fixed, flexible guidewire at the tip. In the second period, an independent, steerable guidewire and the steerable catheter system were used. In the third period, low-profile catheters were introduced. A total of 2,969 patients who had single-vessel PTCA of a native coronary artery was separated into groups according to the period during which PTCA was performed. Introduction of the steerable catheter system was accompanied by improvement in primary success rate in PTCA attempts on the right coronary artery (78% vs 88%, p <0.005). Introduction of the low-profile catheter was accompanied by improved primary success in PTCA attempts on the left anterior descending coronary artery (LAD) (90% vs 94%, p <0.005). The percentage of PTCA attempts on the LAD decreased over the 3 periods (70% to 60% to 56%), while the percentage of attempts on the left circumflex artery increased (7% to 12% to 16%). Before steerable and low-profile catheters were used, there were significant differences in ability to reach and cross stenoses among the 3 major coronary arteries. These differences no longer exist. These results indicate that technical improvements and operator experience have made stenoses in all 3 major coronary arteries equally accessible to dilatation catheters and that primary success rates and reasons for failure in these arteries are now similar.

(Am J Cardiol 1985;56:712–717)

Primary success in percutaneous transluminal coronary angioplasty (PTCA) depends on many factors. Patient selection, lesion location, operator experience and equipment choice all play important, but ill-defined, roles.[1–4]

Catheter systems for positioning the angioplasty balloon at the site of stenosis have evolved. Three distinct periods can be identified. In the earliest period, the coronary dilatation catheter was a double-lumen, balloon-tipped catheter with a fixed, flexible guidewire at the distal end, just in front of the balloon.[5] Single, discrete stenoses of the proximal portion of a major coronary artery were the most amenable to successful dilatation.[6]

The second period in coronary dilatation catheters began with the introduction of the independent, steerable guidewire.[7] Torque control and flexibility, superior to the plastic shaft of the original dilatation catheters, permitted the steerable guidewire to be maneuvered into all major coronary arteries and their branches. Once the guidewire was in position the dilatation catheter could be advanced over it. Simultaneous traction on the guidewire and advancement of the steerable dilatation catheter provided improved backup for maneuvering the balloon across a difficult stenosis.[3,8,9]

The most recent period in coronary dilatation catheters began with the introduction of the low-profile catheter. This system preserved the basic design of the independent, steerable guidewire and accompanying catheter. Guidewires for the low-profile system are smaller (0.012 or 0.014 inch vs 0.016 inch), and the balloon tip has a smaller overall dimension.

We undertook this study to determine if changes in the primary angiographic success rate of PTCA at our institution are related to these changes in catheter design.

Methods

Patient selection: From July 14, 1980, to August 15, 1984, 3,716 patients underwent PTCA at Emory University Hospitals. Excluded from this study were 400 patients who underwent multiple-vessel dilatation and 140 patients who had dilatation of a bypass graft. Of the remaining 3,176 patients, 15 had incomplete or ambiguous records. Thus, 3,161 patients who underwent single-vessel dilatation of a native coronary artery formed the population base.

To accurately study changes in primary success rate, we examined the number of native-artery single-vessel PTCA procedures performed and the primary success rates for the

From Emory University School of Medicine, Atlanta, Georgia. Dr. Roubin is an Overseas Research Scholar of the National Heart Foundation of Australia. Manuscript received April 8, 1985; revised manuscript received May 23, 1985, accepted May 24, 1985.

months after the start of PTCA at our institution. This examination (Fig. 1) revealed an initial steep rise in the primary success rates. To prevent early results from biasing the analysis, we excluded the first 192 patients of our base population or patients whose PTCA procedures were performed before June 1, 1981 (Fig. 1, point A). We therefore restricted the analysis to 2,969 patients undergoing native single vessel PTCA, from June 1, 1981 to August 15, 1984.

Data collection: Since 1980, information on all patients undergoing PTCA at our institution has been collected prospectively. Patient history, physical examination, laboratory studies and PTCA procedure characteristics are recorded on standard forms. After audit for completeness by a research nurse, the data are entered into the cardiac data bank central computer (VAX 11/750, Digital Equipment Corp.).

Angiographic measurements: The angiographic severity of a coronary artery lesion was determined as percent diameter stenosis. Measurement of cineangiograms was done with a programmable digital caliper system (Prodical 1101, A2D Ultrasound, Inc.). In each available projection the frame showing the most severe stenosis in end-diastole was chosen for measurement. The percent diameter stenosis recorded was the mean value of the measurements from 2 or 3 available projections (right anterior oblique, left anterior oblique and lateral). This method has been shown to reduce observer variability.[10]

Lesion length was determined from the same angiographic frames as percent diameter stenosis. Caliper measurements were made of the lesion from the point of first tapering to the point of last widening of the vessel lumen. A calibrated scale allowed translation of measurements into millimeters. The lesion length recorded was the longest of the measurements made in the available projections.

The presence or absence of increased radiodensity within the body of the lesion was noted at the time of cineangiographic review. This result was recorded either as a calcified or noncalcified lesion.

Gradient: Aortic pressure was monitored and recorded from the coronary artery guide catheter. Distal coronary artery pressure was monitored and recorded from the central lumen of the angioplasty balloon catheter. Pressures were determined with tubing filled with saline solution, and strain gauge transducers (Statham P23ID). An automated recording system was used (MEDARRS, Honeywell, Inc.). When the angioplasty balloon catheter was in place at the site of narrowing the difference between aortic and distal coronary artery pressures was monitored and recorded as the transstenotic pressure gradient.

Vessels: The location of a stenosis in 1 major coronary artery or its branches was noted on a coded diagram. For this study all PTCA procedures were grouped according to major coronary artery. A PTCA procedure attempted in a branch of a major coronary artery was therefore grouped by the artery off of which it branched, either left anterior descending (LAD), left circumflex (LC) or right coronary artery.

Success and failure: Primary success in PTCA was defined angiographically as a reduction of at least 20 percentage points in the percent diameter stenosis, determined from measurements of cineangiograms before and after the PTCA procedure. Angiographic success only, rather than clinical and angiographic success, was considered in this study. All unsuccessful PTCA attempts were recorded in 1 of the following mutually exclusive categories: unable-to-reach lesion, unable-to-cross lesion and no-reduction-in-stenosis, meaning that a reduction of less than 20 percentage points in percent diameter stenosis was achieved.

Catheter systems (Fig. 2): From July 1980 through April 1982, PTCA was performed at our institution using a double-lumen balloon catheter (USCI) with a fixed, flexible guidewire at the tip (Fig. 2A). In April 1982 the steerable catheter system (USCI) with an independent, steerable guidewire was introduced (Fig. 2B and C). By May 1982 the steerable catheter was used exclusively for all PTCA procedures. In July 1983 the low-profile catheter (USCI), which maintained the design of the steerable catheter but was smaller in dimension at the balloon tip (Fig. 2D), became available at our institution. The low-profile catheter was used in all cases in which a stenosis was judged too severe to accommodate a standard balloon catheter. It was also used in a catheter exchange whenever a standard balloon catheter could not be passed through a stenosis.

Time periods: The study period from June 1, 1981, to August 15, 1984, was separated into 3 intervals to correspond with the time periods in which the 3 catheter systems were in use: period I (original double-lumen catheter)—June 1, 1981, to April 14, 1982; period II (steerable catheter system)—April

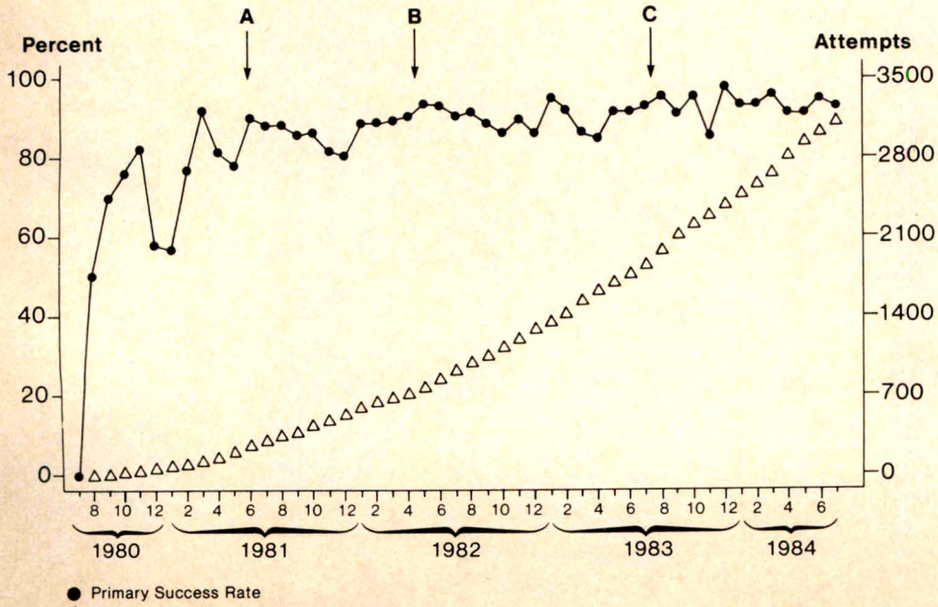

FIGURE 1. Primary success rate in single-vessel percutaneous transluminal coronary angioplasty of a native coronary artery—monthly data. A = end of learning curve; B = introduction of the steerable catheter system; C = introduction of the low-profile catheter.

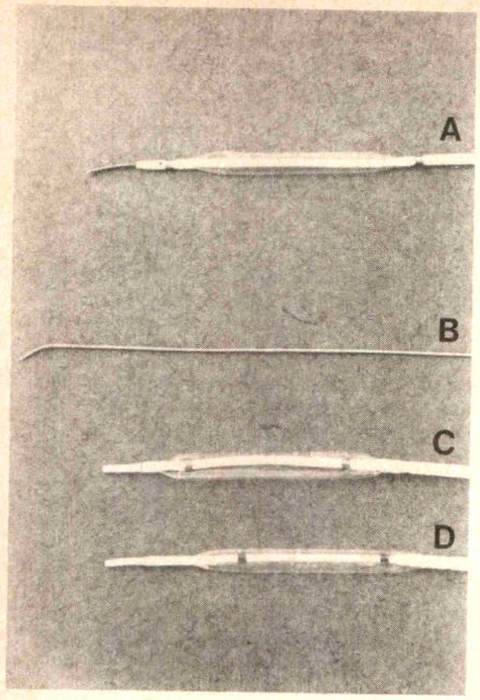

FIGURE 2. A, original fixed guidewire angioplasty catheter. **B,** steerable guidewire. **C,** steerable catheter. **D,** low-profile catheter.

15, 1982 to July 15, 1983; and period III (low-profile catheter)—July 16, 1983, to August 15, 1984.

Statistical analysis: Variables were compared from period I to period II (before and after introduction of the steerable catheter), period II to period III (before and after introduction of the low-profile catheter) and, when appropriate, from period I to period III (earliest experience to most recent experience). Unsuccessful PTCA attempts were compared among the 3 major coronary arteries within each time period. Discrete categorical variables were analyzed with the chi-square test. Continuous variables are shown as mean ± standard deviation and were analyzed with a Student *t* test. A p value <0.05 was considered significant.

Results

The separation of the study period into intervals based upon catheter type resulted in 3 intervals of unequal length and unequal number of PTCA attempts. Period I, from June 1, 1981, through April 14, 1982, consisted of 10.5 months and 499 PTCA attempts (Fig. 1, point B). Period II, from April 15, 1982, through July 15, 1983, consisted of 15 months and 1,137 PTCA attempts (Fig. 1, point C). Period III, from July 16, 1983, through August 15, 1984, consisted of 13 months and 1,333 PTCA attempts.

Proportions (Fig. 3): In each of the 3 periods the proportion of single-vessel PTCA attempts in the 3 major coronary arteries varied. The LAD accounted for the majority in each period, but its percentage of the total fell significantly. The right coronary artery accounted for nearly one fourth of all PTCA attempts in each period, and its share did not change significantly. The LC share of total PTCA attempts increased significantly in each period, from 7% in period I to 12% in period II to 16% in period III.

Success and failure in each time period: The total number of PTCA attempts, number of primary successes, number and category of failures, and their corresponding percentages are shown in Table I.

When the 3 coronary arteries are considered collectively, the primary success rate was 88% (436 of 499 attempts) in period I, 90% (1,021 of 1,137) in period II and 92% (1,233 of 1,333) in period III. The change from the fixed guidewire to the steerable catheter (period I to II) caused a trend toward a decline in the percentage of lesions unable to be reached from 3% to 2%. There was no significant change in the other 2 failure categories. The addition of the low-profile catheter (period II to period III) was accompanied by no change in ability to reach a lesion, but a trend toward declines in both unable-to-cross and no-reduction-in-stenosis to 3% each. The change that occurred between periods I and III was significant ($p < 0.01$). During these same periods, the mean percent diameter stenosis of lesions attempted increased very slightly but significantly. The mean

NRS = no reduction in stenosis; NS = not significant; UTC = unable to cross lesion; UTR = unable to reach lesion.

transstenotic pressure gradient and percentage of lesions noted to be calcified did not change. The mean lesion length first increased then decreased, but was higher in period III than in period I.

Success and failure in each vessel: Left anterior descending coronary artery (Table II): The change from the fixed guidewire system to the steerable catheter (period I to period II) was not accompanied by changes in primary success. The mean lesion length was significantly longer in period II than in period I. With use of the low-profile catheter (period III), the primary success rate increased significantly and the failure rates decreased in all 3 categories. Also noted after introduction of the low-profile catheter were increases in mean percent diameter stenosis and the percentage of lesions noted to be calcified. There was a small decline in mean lesion length.

Left circumflex artery (Table III): Neither the introduction of the steerable catheter nor the addition of the low-profile catheter resulted in significant changes in primary success or failure categories. The mean lesion length increased after the introduction of the steerable catheter (period II).

Right coronary artery (Table IV): The introduction of the steerable catheter was accompanied by a significant increase in primary success, with a large decline in the percentage of lesions in the unable-to-reach category and a smaller decline in the percentage in the unable-to-cross category. Use of the steerable catheter was also associated with a significant increase in mean lesion length. The addition of the low-profile catheter was not accompanied by significant changes in primary success or failure categories.

Comparison of vessels within each time period (Table V): In period I (fixed guidewire system), the ability to reach lesions in the 3 major coronary arteries was significantly different (unable-to-reach = 8% for right vs 2% for LAD and none for LC). This difference

TABLE V Comparison of Unsuccessful Attempts at Percutaneous Transluminal Coronary Angioplasty Within Each Time Period

Vessel	Period I	Period II	Period III
	Unable to Reach Lesion		
LAD	2%	2%	1%
LC	0%	1%	3%
RCA	8%	1%	2%
	p <0.01	p = NS	p = NS
	Unable to Cross Lesion		
LAD	4%	3%	2%
LC	9%	5%	4%
RCA	10%	7%	5%
	p <0.05	p <0.05	p = NS
	No Reduction in Stenosis		
LAD	4%	5%	3%
LC	0%	1%	4%
RCA	4%	4%	2%
	p = NS	p = NS	p = NS

LAD = left anterior descending coronary artery; LC = left circumflex artery; NS = not significant; RCA = right coronary artery.

was not apparent after the introduction of the steerable catheter, and the percentage of unable-to-reach lesions for periods II and III was similar for all vessels (Table V). Before the introduction of the low-profile catheter (periods I and II), there was a significant difference among the 3 major coronary arteries in ability to cross a lesion. This difference was not apparent with use of the low-profile catheter (Table V). The no-reduction-in-stenosis category has not been significantly different among the 3 major coronary arteries for any period (Table V).

Discussion

This study demonstrates that the primary angiographic success of PTCA in single vessel lesions of a native coronary artery has increased significantly over 4 years. Angiographic success has increased in conjunction with increases in complexity of lesions attempted. Improvements in primary success and reasons for failure vary among each of the 3 major coronary arteries. Because of technical improvements (the steerable catheter system and the low-profile catheter), PTCA attempts in all 3 coronary arteries now have similar success rates and reasons for failure. This study has dealt only with primary angiographic success; however, acute complications of PTCA have declined during these same periods.[11]

Registry data: The only other large scale compilation of data on PTCA was that of the National Heart, Lung, and Blood Institute PTCA Registry.[12] This registry contains data on single- and multiple-vessel PTCA attempts from September 16, 1977, to September 30, 1982 (3,079 patients).[1] Early data from our institution was included in the registry but we contributed only 190 patients between June 1, 1981, and registry closure to single-vessel PTCA data on October 1, 1981. The registry data thus serves as a useful comparison. A significant proportion of patients in the registry had multiple-vessel PTCA attempts, whereas the present analysis includes only single-vessel attempts.

Learning curve: Our study supports registry data for the presence of a PTCA learning curve.[1,2] Registry data show that primary success increases linearly over the first 250 investigator attempts. However, registry data were being collected at the time the steerable catheter system was introduced (1981 to 1982). Our data show (Fig. 1) that the learning curve effect exists in the early performance of PTCA even when confined to 1 catheter type (in this case the fixed guidewire model). We specifically excluded from our later analysis these early PTCA attempts, which represent the steeply rising portion of the learning curve. The monthly primary success rates after we began our analysis (June 1, 1981) do not exhibit abrupt changes characteristic of a learning curve even at the points where the steerable catheter and the low-profile catheter came into use. However, the proportion of attempts in the 3 major coronary arteries varied between periods. The percentage of PTCA attempts in the LAD fell significantly, while that in the LC increased. This suggests that the "learning curve" changed from a simple success-vs-failure categorization to one of expanded opportunity for attemping angioplasty in the different coronary arteries, particularly the LC.

Steerable catheter system: The advent of the steerable catheter brought about a reduction in the percentage of PTCA failures owing to inability to reach coronary artery lesions. This was entirely a result of improvement in right coronary artery attempts. In addition, the length of coronary artery stenoses attempted increased after introduction of the steerable catheter, with no decline in primary angiographic success. The value of the steerable catheter was anticipated.[2–4,13] The introduction of the steerable catheter was also accompanied by a decline in the percentage of failures owing to inability to cross the coronary artery stenosis, again particularly in LC and right coronary artery lesions (Tables I, II and III). This suggests that the steerable guidewire was superior to the older, fixed guidewire system for crossing lesions even once they were reached. The ability to steer a guidewire into distal branches of the coronary artery before balloon catheter placement may provide the backup needed to cross more difficult lesions.

Low-profile catheter: As would be expected, use of the low-profile catheter brought about a decline in the percentage of failures owing to inability to cross the lesion. Although lesion length declined slightly after introduction of the low-profile catheter, mean lesion length was still longer than in the earliest period. The mean percent diameter stenosis increased slightly but significantly, and it increased most in the LAD, which had the largest increase in primary angiographic success after introduction of the low-profile catheter (Table II).

Inability to reduce the stenosis: Neither the introduction of the steerable catheter nor the addition of the low-profile catheter had an effect on the percentage of failures owing to inability to reduce the stenosis in any of the 3 vessels. The registry data demonstrated a correlation between a decline in inability to dilate and increased mean balloon inflation time and mean maximum number of inflations.[2,4] Other investigators have

suggested that primary success may be improved by these 2 measures.[14] We did not collect these data from our patients.

The constancy of the no-reduction-in-stenosis category in our data may be related to the finding that overall, the percentage of lesions noted to be calcified remained constant across the 3 periods, and the influence of calcified lesions would probably be detected in this category. Calcification of a lesion very likely reflects its age and degree of distensibility. Additionally, the registry has identified lack of lesion calcification as both a univariate and multivariate predictor of success.[4]

Vessel differences: Right coronary artery lesions have consistently had the highest mean percent diameter stenosis, highest mean transstenotic pressure gradient and longest mean lesion length (Table IV). Despite this, primary angiographic success in right coronary artery lesions has improved the most and now almost equals primary success in LAD lesions. In addition, the left circumflex artery has become accessible to dilatation equipment and its proportion of overall PTCA attempts is increasing.

In conclusion, technical changes have occurred in PTCA, which are reflected in improved primary angiographic success. These changes along with operator experience have made stenoses in all 3 major coronary arteries equally accessible and the reasons for dilatation failure similar. This improvement occurred even as more difficult lesions were selected for attempted angioplasty.

Digital Quantification Eliminates Intraobserver and Interobserver Variability in the Evaluation of Coronary Artery Stenosis

RAN VAS, PhD, NEAL EIGLER, MD, CALVIN MIYAZONO, MS, J. MARTIN PFAFF, BS, KENNETH J. RESSER, BA, MASON WEISS, MD, THASANA NIVATPUMIN, MD, JAMES WHITING, PhD, and JAMES FORRESTER, MD

A leading problem with subjective interpretation of coronary angiography is high intraobserver and interobserver variability. Four experienced angiographers independently determined percent diameter narrowing of 36 stenoses using 3 methods: by subjective analysis of single-frame cine film images (film), by subjective analysis of digitized nonenhanced single-frame images (digital), and by using a semiautomated digital caliper quantification system (Corona). The reproducibility of interpretations was assessed by comparison of estimated intraclass correlation coefficients. Digital and Corona readings correlated well with subjective interpretation of film ($r > 0.85$ for both). In contrast to Corona, the angiographers systematically overestimated the magnitude of stenoses in the intermediate (50 to 75%) range. Corona markedly improved intraobserver ($p < 0.005$) and interobserver ($p < 0.001$) reproducibility. Corona less frequently misclassified individual observations than did film when categories of less than 50%, 50 to 75% and more than 75% diameter stenosis were used (3.7% vs 31.5%, $p < 0.001$). Our results suggest that digitization of a coronary angiogram in a 512 × 512 matrix has no significant adverse effects on the perception and quantification of stenosis by angiographers. Additionally, automatic measurement of coronary stenosis has 2 major advantages: It is accurate compared with a group of experienced angiographers and for the practical purpose of clinical decision-making, it eliminates intraobserver and interobserver variability.

(Am J Cardiol 1985;56:718–723)

A leading problem with conventional coronary angiography is that intraobserver and interobserver variability of subjective interpretation of stenosis severity is high.[1–7] Although automated measurement of stenosis by digital processing has the potential to decrease observer variability, 2 important questions must be resolved before such a program is developed. First, transformation of a cineangiographic image to a digitized format carries the risk of loss of resolution, which can cause errors in evaluation of stenosis. Second, there are no data that establish the superiority of automated processing in reducing intraobserver and interobserver variability for the specific task of quantifying percent stenosis. The goals of this study were to determine the effect of digitizing cine film images upon the visual estimation of stenosis severity and to assess the impact of computer-assisted measurement on the reproducibility and accuracy of interpretation.

Methods

Data base: Single-frame images of 36 coronary stenoses were obtained from 11 patient cineangiograms. Stenoses with 0 to near 100% luminal diameter narrowing were selected. Five stenoses were in the left main artery, 10 were in the left anterior descending artery, 7 were in the left circumflex artery and 14 were in the right coronary artery. No selection was made with regard to the timing of the frame within the cardiac cycle, the projection, film quality, or whether stenoses were discrete, part of a diffusely diseased artery, concentric or eccentric.

Digital images were obtained by viewing each single-frame cine film image with a television camera (RCA 1005 Vidicon), which served as input to an ADAC 4100C digital angiography system. Digital images were acquired in a 512 × 512 pixel matrix format with 256 gray levels of intensity, without magnification, contrast enhancement or filtering.

Image analysis: Quantification of percent diameter stenosis was performed by 4 experienced angiographers using 3 different methods: visual estimation from both cine film (film) and digital images (digital) and digital caliper measurement from digital images. Each angiographer evaluated percent diameter stenosis of all 36 lesions independently on 9 separate occasions, 3 times for each of the 3 methods (total of 1,296 readings). The general region of the coronary artery which included the stenosis to be analyzed was denoted by an arrow on a celluloid overlay. The angiographers received no instructions other than to visually estimate percent diameter

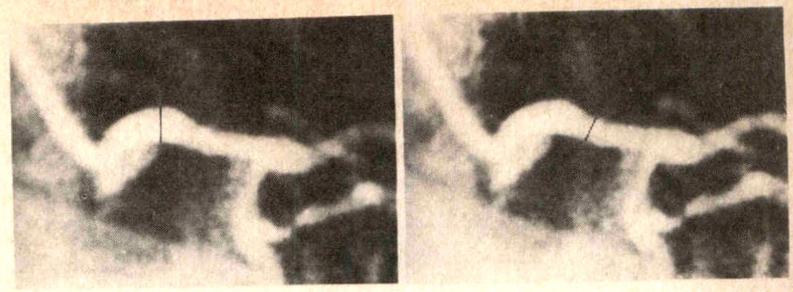

FIGURE 1. Demonstration of Corona. Both panels show the television monitor picture of the same digital coronary image acquired from cine film. The angiographer has placed and adjusted a line segment across what he considers to be the normal artery diameter (**left**) and the maximally stenotic diameter (**right**). Percent diameter stenosis is calculated automatically from the lengths of these segments.

narrowing. Film images were presented on a Vanguard rear projection system. Digital images were viewed on an Ikegame 17-inch black/white monitor. The angiographers were allowed to adjust the light intensity on the film projector and the brightness and contrast controls on the television monitor. Reading sessions were held at least 1 week apart and the sequence of stenoses and the reading format were varied.

For computerized analysis of coronary stenosis, we developed an interactive computer program, which we named Corona (Fig. 1). Corona first magnifies the stenosis region 2 times without changing the gray scale. Using a light pen and keyboard, the angiographer is then prompted to place 2 cursor points across what he considers to be the normal artery diameter and repeats this procedure for the region of maximal coronary narrowing. The length of each diameter segment can be resolved to 1 pixel. Each pixel represented between 0.22 and 0.46 mm, depending on the magnification of the radiographic imaging system. Percent diameter stenosis was calculated as the diameter across the region of maximal narrowing divided by the diameter of the normal segment. Location of the normal and stenotic regions were determined by the angiographer and no additional image processing was permitted.

To assess the accuracy and reproducibility of Corona measurement compared to objects of known dimension, we produced a digital radiographic calibration image of a phantom consisting of 6 drill rods ranging in diameter from 1.02 to 9.92 mm. These rods were positioned with their long axes in a radial arrangement and were imaged at 70 kVp, 300 mA with a 6-ms exposure using a 6-inch image intensifier. All 4 angiographers used Corona on 3 occasions to evaluate the diameter in pixels of each phantom object. No correction for image pincushion distortion was made and no instructions were given regarding where to measure the test objects.

Data analysis: Comparisons for relative accuracy between the 3 methods of quantifying percent stenosis were made by linear regression analysis.[8]

Intraobserver and interobserver reproducibility of each method was quantified by computation of estimated intraclass correlation coefficients. Intraclass correlation coefficients were calculated from a 1-way analysis of variance for repeated measures.[9,10] These coefficients can range from 0 to 1.0 and approaches 1.0 as the agreement between interpretations improves. The intraclass correlation coefficients for intraobserver and interobserver reproducibility for each method were compared using Fisher's Z transformation and chi-square statistics.[11] Throughout the text, pairwise testing between methods (p values) have been adjusted for multiple comparisons.

To assess the potential impact of computerized analysis on clinical decision-making, the frequency with which an individual reading misclassified stenoses was compared for each method. Stenoses were categorized as less than 50%, 50 to 75% and more than 75% diameter narrowing, based on the mean value of the 12 readings determined with each of the 3 methods.

Results

Phantom validation: Corona analysis of the calibration image showed a strong linear correlation between the mean observed diameter vs the true diameter of the 6 test objects [Observed(pixels) = 3.3 × True(mm) + 0.3; r = 0.99]. Thus, each pixel represented 0.3 mm, which was within the range expected in the clinical images. Additionally, the variability of Corona measurements was small; more than 95% of observations were within 1.2 pixels of the mean for each object. Therefore, variability closely approached the spatial resolution of the entire imaging system.

Method comparisons: To establish that the 3 methods exhibited broad agreement as measurement techniques, the mean percent luminal diameter narrowing for all 36 stenoses was determined. For film images the mean (± standard deviation) diameter stenosis was 59.1 ± 22.7%. This was not significantly different from the mean percent stenosis determined by the digital or the Corona methods: 60.8 ± 25.6% and 55.5 ± 21.3%, respectively.

Figure 2 is a comparison of the mean percent stenosis for visual estimation of individual lesions displayed by digital and film methods. These 2 methods showed a strong linear correlation (r = 0.93) and the regression equation (y = −1.0 + 1.0x) did not differ statistically

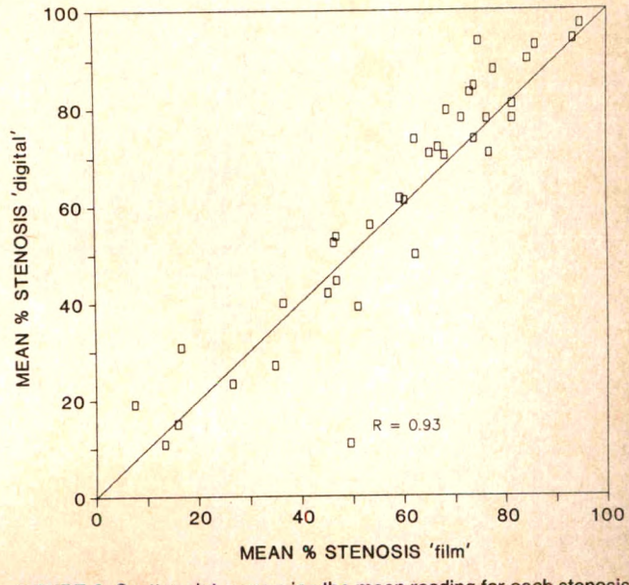

FIGURE 2. Scatter plot comparing the mean reading for each stenosis as estimated from digital images and cine film images.

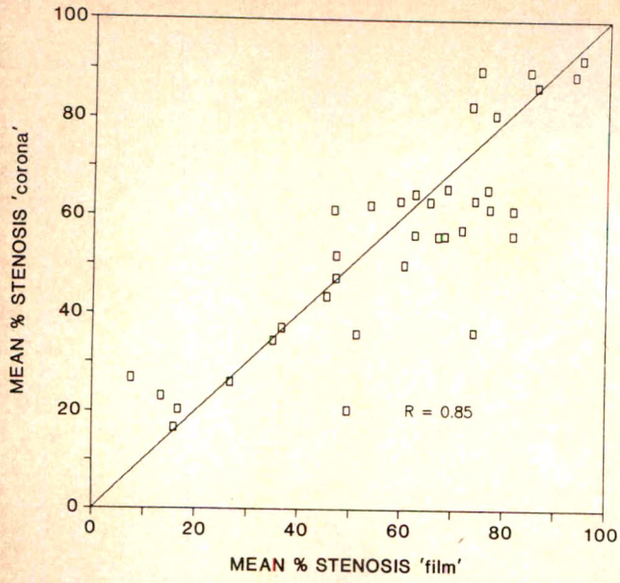

FIGURE 3. Scatter plot comparing the mean reading for each stenosis as measured by Corona with visual estimation from cine film.

from the line of identity. Thus, the accuracy of the interpretation of digital images using conventional film reading as a standard, was high. Agreement between the 2 methods for a given stenosis was good; 97% of stenoses read from digital images agreed with film reading within 18% diameter stenosis. These data suggest that digitization of film images had no systematic effect on the visual estimation of stenosis severity.

Figure 3 shows the comparison of Corona to film reading. Although the correlation coefficient was r = 0.85, the regression line was significantly different from the line of identity ($y = 8.4 + 0.8x$, $p < 0.05$). A systematic difference was found between the 2 methods: stenoses between 50 and 75% by Corona were interpreted to be more severe on film in 12 of 17 instances.

Comparisons between Corona and digital images revealed similar systematic differences ($r = 0.91$, $y = 9.3 + 0.8x$). This latter result suggests that the method of quantification, rather than the process of image digitization, was responsible for the systematic differences.

Reproducibility: Figure 4 demonstrates the spread of all observations, for each method of quantifying stenosis. Variability in the visual estimation of both film and digital images was substantial: the average standard deviation per stenosis were 12.6 and 10.7%, respectively. This variability was greatest between 50 to 75% stenosis. The largest difference in subjective interpretation of an individual stenosis was 0 vs 95%. In comparison, the variability of stenosis measurements using Corona was narrow. The mean standard deviation was 3.8% and variability was evenly distributed for stenoses of all severities.

An example of intraobserver variability is shown in Figure 5. The spread of the 3 interpretations for each of the 36 stenoses by observer 2 is shown for his film and

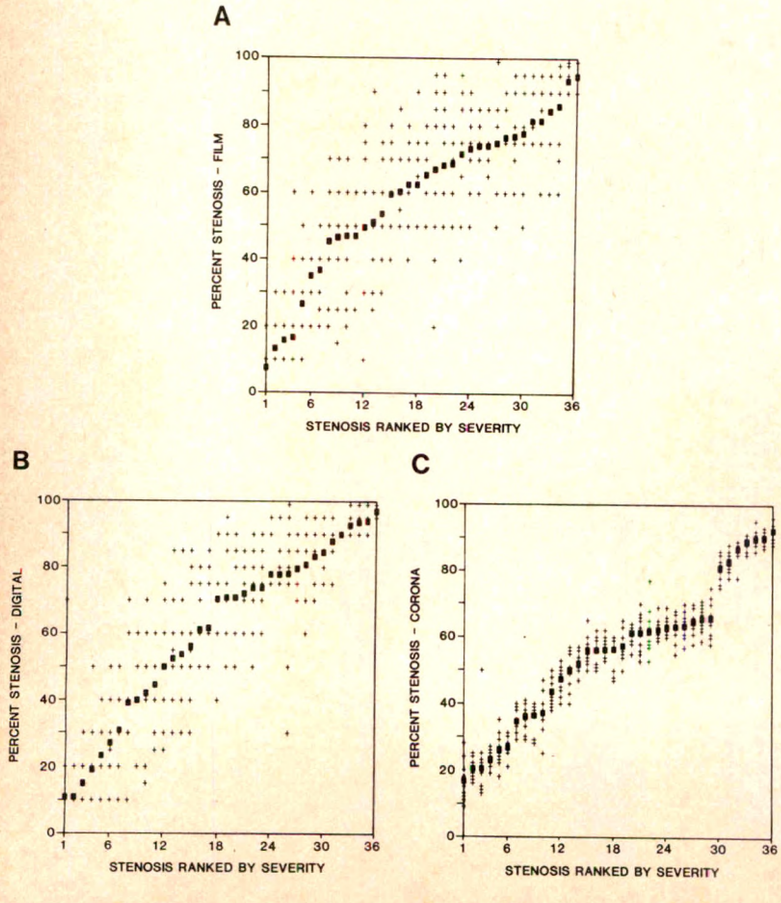

FIGURE 4. Distribution of individual observations (**plus signs**) for each stenosis by film, digital and Corona methods (**A, B** and **C,** respectively). Stenoses are ranked by mean severity. The sum of plus signs per vertical column appears less than 12 where readings coincide.

Corona readings. The results are typical of all 4 observers in 2 respects. First, Corona interpretations displayed much less variability. Second, for subjective film interpretation, variability was greatest for stenoses of moderate severity, whereas with Corona, variability was evenly distributed.

The differences in intraobserver reproducibility, as quantified by intraclass correlation coefficients, are shown in Table I. For each angiographer, the intraclass correlation coefficients for stenoses evaluated by Corona was greater than that for film. Since no significant differences between angiographers were found, we used mean intraobserver intraclass correlation coefficients as a composite index of intraobserver reproducibility. The difference between film and Corona methods was highly significant ($p < 0.005$).

Figure 6 shows the interobserver variability by stenosis from film and Corona readings. The mean of each angiographers 3 readings per stenosis are plotted for each method. For film readings, observer 1 consistently overestimated the severity of stenoses in relation to the other angiographers. Despite the tendency to improve interobserver agreement by comparing angiographer's mean readings, rather than first readings, film readers disagreed on stenosis severity by more than 20% for 25 of the 36 stenoses. In comparison, when the same readers used digital quantification with Corona, they agreed within 10% for all 36 stenoses and there was no systematic differences between individual angiographers. Interobserver reproducibility as assessed by intraclass correlation coefficients was significantly greater for Corona than for film (0.97 vs 0.76, $p < 0.001$).

Clinical classification: To assess the clinical significance of differences in interpretation of the severity of stenosis, each stenosis was categorized as less than 50%, 50 to 75% and more than 75% stenosis, based on its mean value for the same method of interpretation. An individual interpretation was then defined as a misclassification if it did not fall in this category. Figure 7 shows the frequency of misclassification for each method of interpretation. Stenoses were misclassified significantly less often with Corona (3.7%) than with visual estimation from Digital (26.4%) or film (31.5%) images ($p < 0.001$ for both comparisons). This pattern was consistent within each category of stenosis severity.

TABLE I Intraobserver Reproducibility

Observer	1	2	3	4	Mean
Film	0.88	0.79	0.88	0.86	0.85
Corona	0.98	0.96	0.98	0.98	0.98
					$p < 0.005$

Assessment of intraobserver reproducibility by estimated intraclass correlation coefficients. Reproducibility improves as coefficients approach 1.0.

Discussion

A leading problem with coronary angiography is the high intraobserver and interobserver variability of subjective interpretation of stenosis severity. As in our study, Bjork et al[1] reported complete agreement between 4 observers in only 37% of coronary angiographic interpretations, and in 40% of the observations, variability was greater than 20%. This lack of agreement in the subjective interpretation of coronary angiograms has been repeatedly confirmed.[2–6] Poor reproducibility may cloud the relationship of coronary anatomy with

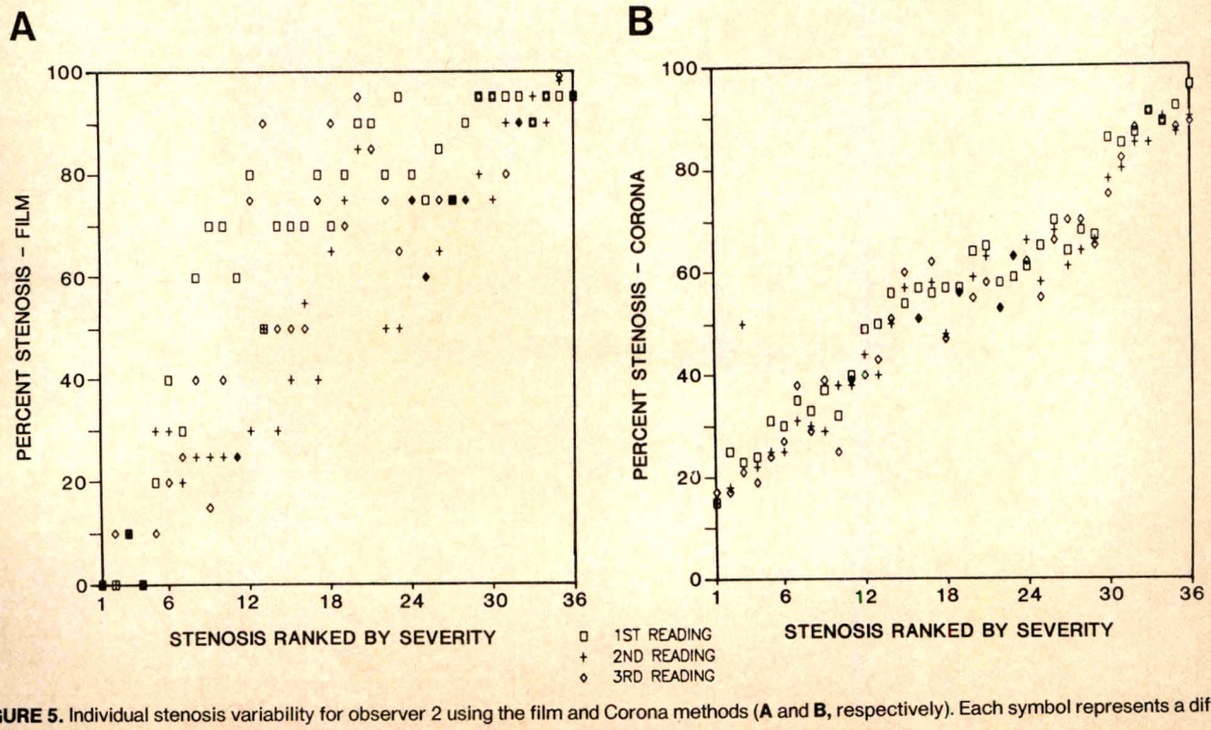

FIGURE 5. Individual stenosis variability for observer 2 using the film and Corona methods (**A** and **B**, respectively). Each symbol represents a different reading.

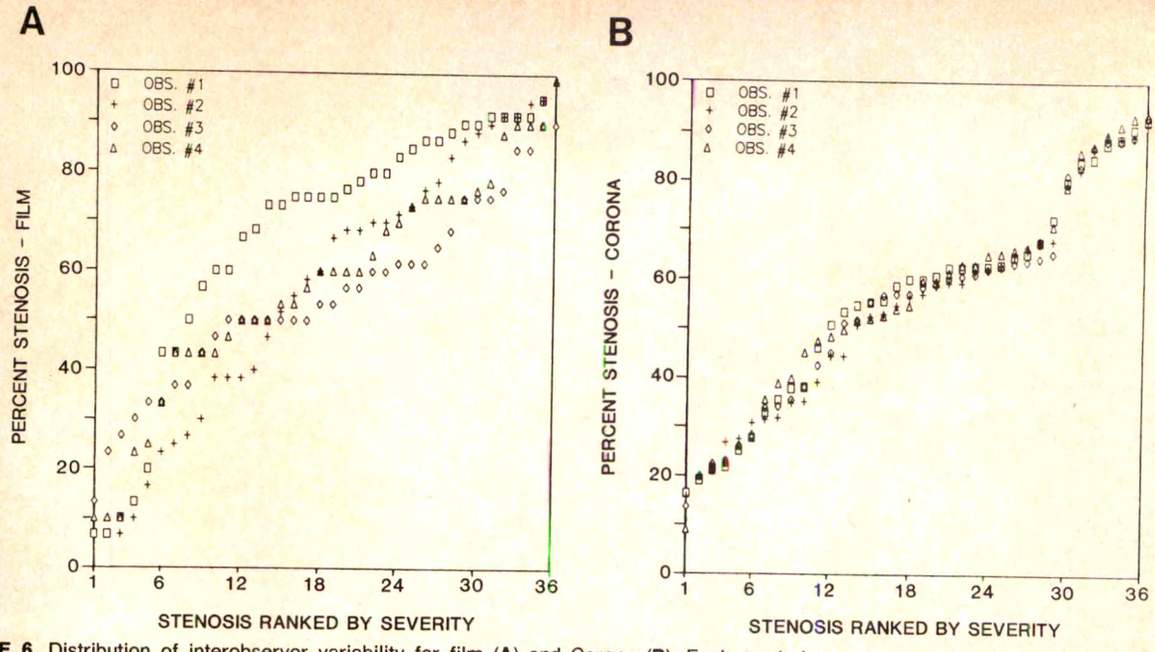

FIGURE 6. Distribution of interobserver variability for film (**A**) and Corona (**B**). Each symbol represents the mean of 3 readings by each observer.

prognosis in important clinical investigations. For example, in the Coronary Artery Surgery Study (CASS), interobserver disagreement between normal and more than 50% diameter narrowing occurred in 15% of the coronary arteries studied.[7] Interobserver reproducibility may be improved by the use of broad categories[12]; however, Galbraith et al[6] found an 18% misclassification rate using the broadest possible categories (greater or less than 50% diameter stenosis).[6] Although a potential solution may be to use consensus readings, Galbraith et al found that when misclassification occurred, the same error was made by at least 2 of the 3 observers in more than 50% of the cases. These data establish the need for a simple, less subjective, more reproducible technique for quantifying coronary stenosis severity.

Digital image processing has the potential to sharply reduce the variability demonstrated in subjective interpretations. However, there are insufficient data establishing that automatic processing increases either the reproducibility or accuracy of interpretation, or that the magnitude of the improvement obtainable would have any importance in clinical practice. Additionally, the procedure has a major theoretical limitation: Compared with the tiny grains of photographic film, an individual digitized picture element is large. There is potential for both loss of image resolution and for measurement errors. Measurement errors can be compounded by expressing coronary diameters as a ratio. One major goal of this study was to determine whether a conventional 512 × 512 digital pixel matrix caused

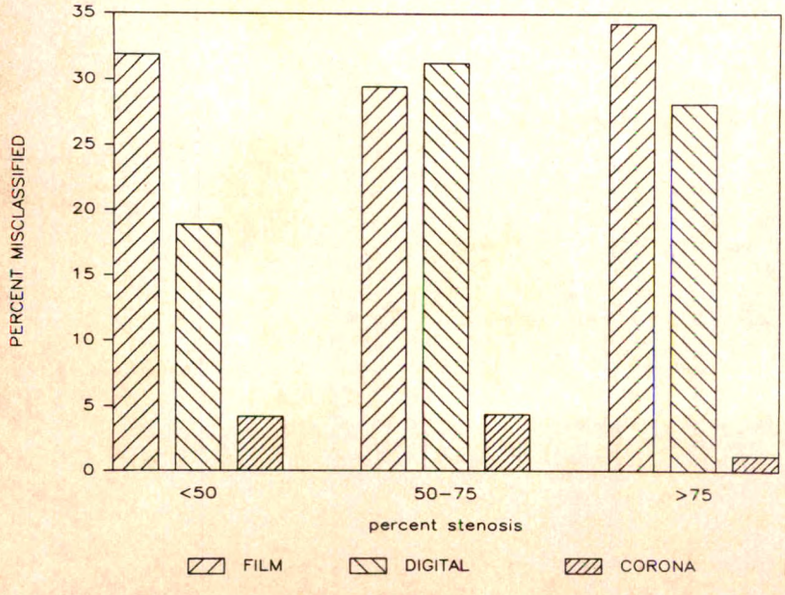

FIGURE 7. Frequency of misclassification by each method. Each stenosis was categorized as less than 50%, 50 to 75% and more than 75% according to the mean of 12 readings for each method. **Bars** represent the frequency with which misclassification of an individual reading occurred for each method. For each category, Corona less often misclassified stenoses in comparison to film or digital methods ($p < 0.01$).

significant loss of image resolution for the specific task of quantifying stenosis.

Effect of digitization on subjective interpretation of stenosis severity: Our data suggest that coronary angiographic images that are digitized in a 512 × 512 pixel matrix are equivalent to cine film for routine clinical use. Direct comparison of film to digital interpretations showed no significant differences. Also, we found that digitization of images before interpretation had no adverse effects on either reproducibility or the rate of clinical misclassification.

The ability of an imaging technique to delineate coronary stenosis depends both on its spatial and contrast resolving powers. Although the spatial resolution of film is 2- to 3-fold greater than a 512 × 512 digital image, its contrast resolution is fixed. Manipulation of television brightness and contrast allows the angiographer additional flexibility. For practical purposes a 512 × 512 pixel matrix appears to be adequate for assessing the severity of coronary stenosis. This is important because higher resolution digital images require more new equipment and software, slow down image acquisition, processing and display rates, and create the need for much larger storage capacity.

Accuracy of digital caliper systems: Computer-assisted quantitation of coronary stenosis was first established by Brown et al[13,14] as both accurate and reproducible in validation studies with x-ray phantoms and postmortem specimens. This method is time consuming and requires cumbersome projection equipment. Scoblionko et al[15] developed an electronic caliper that can be applied directly on projected cine film images and produces measurements of percent diameter stenosis that correlate quite well with the method of Brown et al. Similar to the results of our study, Scoblionko et al[15] found that conventional film reading consistently overestimated stenoses in the 50 to 75% range. Because the actual magnitude of percent diameter stenosis of the arteries in our study were unknown, we can only infer from our phantom data that under controlled conditions, Corona measurements are accurate within 0.3 mm. Absolute measurement of coronary artery diameter is a complex issue because of unresolved anatomic and technical imaging problems. We did not intend in this study to address the accuracy of coronary diameter measurements other than by demonstrating that Corona measurements are comparable to other caliper techniques. In fact, Corona eliminates parallax, improves contrast flexibility, facilitates fine caliper adjustment and ease of caliper placement, which are potential advantages over electronic caliper methods.

Effect of digital processing on reproducibility: Digital caliper quantification of coronary stenosis significantly improved intraobserver and interobserver reproducibility. We confirmed the findings of investigators who showed that subjective interpretation of coronary stenosis severity is highly variable.[1–7] Although intraobserver and interobserver variability for subjective methods were largest for stenoses of moderate severity, with Corona, both intraobserver and interobserver variability were narrow and uniformly distributed, without relation to the severity of stenosis.

Assessment of percent diameter stenosis requires localization of the maximally stenotic segment and the normal region for comparison, perception of the luminal edges, and quantification of these subjective evaluations. Reproducibility may be affected by variability in each of these steps. Digital caliper measurement most certainly reduces quantification error but may additionally improve localization and edge detection variability by forcing the angiographer to evaluate stenoses in a more systematic manner.

Digital quantification made clinical classification more reliable. When we categorized stenoses into the commonly used clinical groupings of less than 50%, 50 to 75% and more than 75% diameter narrowing, 32% of the individual subjective readings of cine film images were misclassified. In contrast, the misclassification frequency using Corona was only 3.7%.

For practical application, digital image processing and quantification was both simple and efficient to use. Once an image is displayed, the entire processes of digitization and quantification takes approximately 30 seconds per stenosis. The information is stored on computer disk and incorporated into a software driven automatic clinical report. Total analysis time per patient is thus comparable to conventional film reading plus report dictation.

Comparison of Buccal Nitroglycerin and Oral Isosorbide Dinitrate for Nitrate Tolerance in Stable Angina Pectoris

JOHN O. PARKER, MD, KAREN A. VANKOUGHNETT, RN, and BERNICE FARRELL, RN

Sixteen patients with chronic stable angina pectoris were studied to compare the hemodynamic and antianginal effects of buccal nitroglycerin (GTN) in a dose of 3 mg administered 3 times daily and oral isosorbide dinitrate (ISDN) in a dose of 30 mg administered 4 times daily. Compared with placebo, both oral ISDN and buccal GTN treatment induced a decrease in systolic blood pressure at rest over a 5-hour period during acute but not during sustained therapy. Neither buccal GTN nor oral ISDN modified the changes in systolic blood pressure during exercise. Both treatment programs were associated with a higher exercise heart rate during acute therapy. During sustained treatment with buccal GTN, the heart rate during exercise remained greater than that during placebo throughout the 5-hour test period, but during treatment with oral ISDN, only the exercise heart rate at 1 hour was greater than that seen with placebo. Treadmill walking time to the onset of angina and to the development of moderate angina increased significantly during acute therapy with both buccal GTN and oral ISDN. The clinical efficacy of buccal GTN was maintained after 2 weeks of 3-times-daily therapy. In contrast, during 4-times-daily therapy with oral ISDN, treadmill walking time was prolonged for only 1 hour after drug administration. This investigation indicates that tolerance develops during 4-times-daily therapy with oral ISDN, but 3 times daily therapy with buccal GTN is not associated with diminished antianginal effects.

(Am J Cardiol 1985;56:724–728)

Isosorbide dinitrate (ISDN) is a useful antianginal agent, but its effects are attenuated during sustained oral therapy.[1,2] Recent studies have shown a similar phenomenon with transdermal ISDN[3] and nitroglycerin (GTN).[4] Reversal of hemodynamic tolerance to oral ISDN has been found after a short washout period,[5] and it has been suggested that intermittent nitrate therapy may be preferable in the management of angina pectoris. Buccal GTN, like sublingual GTN, produces major hemodynamic effects within 60 to 90 seconds of administration[6] and provides protection against angina for as long as the buccal tablet is in place, usually 4 to 6 hours. The present study compares the hemodynamic and antianginal efficacy of buccal GTN and oral ISDN during acute and sustained therapy. The study design permitted assessment of the development of tolerance during therapy with these 2 antianginal agents.

Methods

Sixteen patients (14 men, 2 women), aged 50 to 68 years (average 60.5), with chronic, stable angina pectoris completed this study. Each patient had classic angina pectoris and had a positive treadmill exercise test response, which included the development of angina associated with ischemic ST-segment depression (flat or downsloping ST segments of at least 1 mm for 80 ms after the J point). The diagnosis of coronary artery disease was confirmed by a history of myocardial infarction or by angiographic demonstration of significant coronary artery disease. No patient had cardiomegaly, heart failure, valvular disease, hypertension or heart disease other than coronary artery disease and none was taking digitalis glycosides, β-blocking agents, calcium antagonists or nitrates other than sublingual GTN. Before entering the definitive study, the patients underwent repeated treadmill exercise testing, using the Bruce protocol to familiarize them with the procedure and to determine whether the exercise end point was reproducible. The time to the onset of angina (P_1) was noted and patients were asked to continue exercise until angina was of moderate severity (P_2). During treadmill testing, systolic blood pressure was recorded at the end of each exercise stage and at P_1 and P_2. The CASE Marquette system was used during exercise testing; this system provided data relating to heart rate and ST-segment changes. Over several days, patients exercised on 3 or 4 occasions until the end point (P_2) was reproducible within 90 seconds. Patients whose test results were reproducible and whose total exercise duration was shorter than 9 minutes were considered eligible for this investigation. When reproducibility had been established, exercise testing was carried out 5 minutes after the administration of 0.4 mg sublingual GTN. Patients were considered to be nitrate responders if the time to P_2 was increased by 60 seconds after GTN. Patients entered the definitive investigations when they had reproducible angina pectoris and responded to nitrate therapy.

Definitive investigations (Fig. 1): This was a double-blind, placebo-controlled, crossover study in which patients were assessed during therapy with buccal GTN and oral ISDN. The study was initiated by a 1-week, single-blind period, during which patients received both placebo buccal GTN and placebo oral ISDN. The oral tablets were administered 4 times daily (0700, 1200, 1700 and 2300 hours) and the buccal

tablet 3 times daily (0700, 1200 and 1700 hours). The buccal tablet was placed against the gum above the upper incisor teeth and patients were instructed not to manipulate this with their tongue or finger. If the tablet dissolved before the next scheduled application, they were told to replace the tablet. At the next scheduled dose, the remaining tablet was removed and a new one was placed. Any residual tablet remaining at 2300 hours was removed. On the seventh day patients came to the laboratory without taking their scheduled morning medications and exercise testing was carried out. Patients then received both placebo medications and exercise testing was carried out after 1, 3 and 5 hours. At 5½ hours, 0.4 mg sublingual GTN was administered and exercise testing was carried out after 5 minutes. Patients took their regularly scheduled medication for the rest of that day.

The next morning exercise testing was carried out and then the patients received their first dose of active medications, either oral ISDN (30 mg) or buccal GTN (3 mg) and the alternate placebo. Exercise testing was carried out after 1, 3 and 5 hours. Patients continued to receive active therapy for 2 weeks. The first 3 days was a titration phase, during which patients received either ISDN, 10 mg 4 times daily, and placebo buccal GTN 3 times daily, or buccal GTN, 1 mg 3 times daily and placebo ISDN 4 times daily. During the next 3 days, the dose of ISDN was increased to 20 mg or the buccal GTN to 2 mg. Patients subsequently received the full dose of either ISDN, 30 mg, or buccal GTN, 3 mg with alternate placebos for a period of 8 days. Thus, all patients received active therapy with either ISDN or buccal GTN for a period of 2 weeks. On day 14, patients came to the laboratory without taking the morning medications and underwent exercise testing. The morning medications were then administered and exercise testing carried out at 1, 3 and 5 hours. At 5½ hours the patient was given 0.4 mg of sublingual GTN and exercise testing carried out 5 minutes later.

After this first active treatment phase, the patient entered another 1-week, single blind, double-placebo period. On the seventh day, exercise testing was carried out. The patients then entered the final 2-week active treatment phase. This was identical to the initial active treatment phase, but the alternate active medications and placebos were administered. Testing was again performed at the time of the initial dose of medication and after 14 days of therapy.

Results

For data analysis, the values at each time period during placebo, ISDN and buccal GTN therapy were corrected for corresponding baseline values (i.e., time 0). To assess the effects on days 1 and 14, comparisons were made with the corresponding placebo day. For the analysis of the treatment effects on days 1 and 14, paired t tests were used. To test for tolerance, the difference between day 1 and day 14 was compared for buccal GTN and oral ISDN.

Rest hemodynamics (Table I): During placebo therapy there were no differences in heart rate and systolic blood pressure at rest during the study period, and the values during the placebo days were comparable. Sublingual GTN treatment produced the expected decrease in systolic blood pressure and increase in heart rate when administered at the end of the study periods ($p < 0.001$). On day 1 buccal GTN significantly lowered systolic blood pressure at rest throughout the study period ($p < 0.05$), but on day 14, the values at rest throughout the study period were not significantly different from placebo values. The heart rate at rest after buccal GTN treatment was higher on day 1, but on day 14 only the value at 3 hours was significantly greater than that during placebo treatment ($p < 0.01$). On day 1, ISDN produced a significant decline in the systolic blood pressure at rest ($p < 0.05$) and an increase in heart rate ($p < 0.05$) throughout the 5-hour study period, but on day 14 the changes were not significantly different from placebo.

Exercise hemodynamics (Table I): The systolic blood pressure and heart rate at the end of exercise were similar during placebo therapy throughout the 5-hour study period, and there were no differences between the placebo days. Neither buccal GTN nor oral ISDN had significant effects on systolic blood pressure during exercise over those seen with placebo. Compared with placebo, the heart rate at the end of exercise during therapy with buccal GTN was greater throughout the study period both on day 1 and day 14. In contrast, however, after ISDN administration on day 1, the heart rate at 1 and 3 hours was significantly greater than placebo ($p < 0.01$), but on day 14, only the heart rate at 1 hour exceeded that during placebo treatment ($p < 0.05$).

Exercise testing (Table II, Fig. 2 and 3): Treadmill walking time was similar during the 5-hour study period

* Different from placebo ($p < 0.05$); † different from placebo ($p < 0.01$).
ISDN-1 = first dose of isosorbide dinitrate (30 mg); h = hour; ISDN-14 = first dose of isosorbide dinitrate on day 14 (30 mg); P_1 = time to onset of angina; P_2 = time of development of angina of moderate severity; SL = sublingual; T.GTN-1 = first dose of buccal nitroglycerin; T.GTN-14 = dose of buccal nitroglycerin on day 14 (3 mg); TWT = treadmill walking time.

with placebo therapy and no differences were noted between placebo days. In comparison to placebo, time to P_1 and P_2 was significantly prolonged at 1, 3 and 5 hours after buccal GTN on day 1 and day 14 ($p < 0.05$). Oral ISDN produced a marked improvement in exercise time on day 1 for both P_1 and P_2 over 5 hours ($p < 0.01$), and there were no differences from the values with buccal GTN administration. As with buccal GTN, the improvement in walking time was most marked after 1 hour and lesser effects were seen at 3 and 5 hours. In contrast to the improvement on day 1, the response was markedly attenuated during sustained therapy. On day 14, exercise time to P_1 was improved at 1 hour ($p < 0.01$), but the values at 3 and 5 hours were similar to placebo. Similarly, time to P_2 was significantly greater than placebo at 1 hour ($p < 0.05$) and no effect was seen at 3 and 5 hours. The walking time 1 hour after dosing during sustained therapy with ISDN was significantly less than that seen at 1 hour on day 1 ($p < 0.01$).

ST-segment depression at P_2 was similar during placebo therapy and on days 1 and 14 of ISDN and buccal GTN therapy. The time to 1 mm of ST-segment depression was longer at 1 hour on day 1 and day 14 with buccal GTN than with placebo ($p < 0.01$). The time to 1 mm of ST-segment depression was prolonged 1 and 3 hours after oral ISDN on day 1 ($p < 0.05$) and at 1 hour on day 14 ($p < 0.05$).

Discussion

Tolerance to the vascular effects of the nitrates has long been recognized, and in animal studies have shown that the hypotensive effect of organic nitrates is rapidly attenuated during short periods of administration.[7,8] Munition workers exposed to nitrates in their environment often developed vascular headaches, but within a few days these cleared without therapy.[9] Workers soon learned that tolerance disappeared rapidly, and a weekend out of the factory environment was sufficient to lead to severe headaches on return to work. This "Monday headache" signaled the return of normal vascular responsiveness to the organic nitrates. To prevent this loss of tolerance, some workers applied nitrates to their skin during the weekend to prevent such troublesome symptoms.

Although tolerance is recognized, its relevance to the antianginal effects of the organic nitrates is controversial. Danahy and Aronow[10] and Lee et al[11] failed to demonstrate a reduction in the antianginal effects of oral ISDN after 1 to 5 months of therapy with 120 to 160 mg given in 4 divided daily doses. Likewise, Reichek et al[12] failed to show a diminution of antianginal effects during sustained therapy with GTN ointment. Studies from our laboratory have shown that antianginal efficacy is reduced in magnitude and duration during sustained ISDN therapy.[2] Thus, with initial ISDN dosing, walking time was prolonged for up to 8 hours, but when similar doses were administered 4 times daily for 1 week, the improvement in walking time was reduced in magnitude and protection was reduced to 2 hours.[2] These observations have been confirmed in subsequent studies and it is now well established that during short-term, 4-times-daily ISDN therapy, exercise time is not increased beyond 1 to 2 hours after a dose.[13,14]

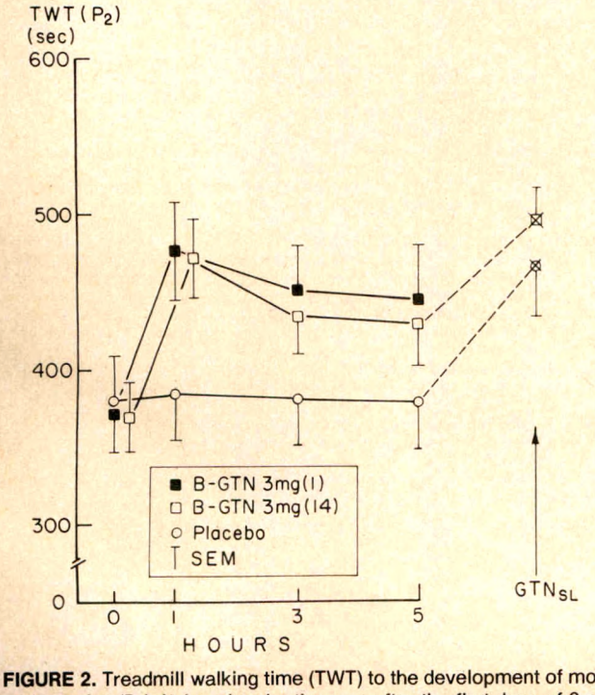

FIGURE 2. Treadmill walking time (TWT) to the development of moderate angina (P_2) during placebo therapy, after the first dose of 3 mg of buccal nitroglycerin (B-GTN 3 mg (1)) and after the same dose on day 14 (B-GTN 3 mg (14)). The response to sublingual GTN (GTN_{SL}) is shown. Values represent mean ± standard error of the mean (SEM). TWT was significantly prolonged over placebo ($p < 0.01$) at each testing time during acute and sustained therapy.

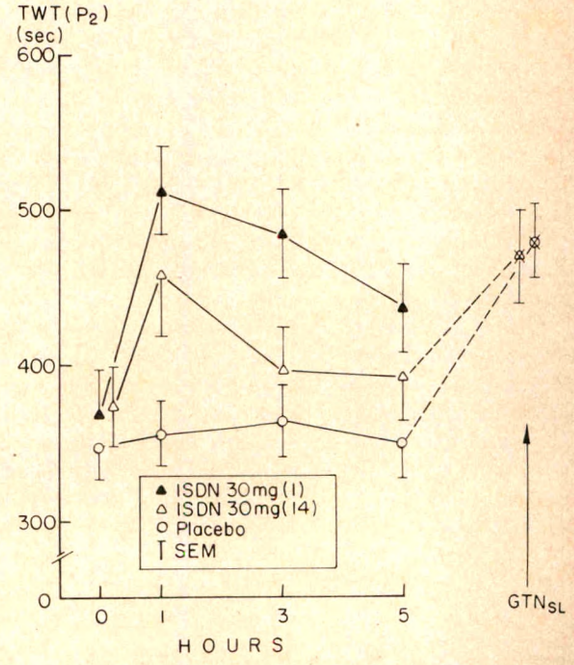

FIGURE 3. Treadmill walking time (TWT) to the development of moderate angina (P_2) during placebo therapy, after the first dose of 30 mg of isosorbide dinitrate (ISDN 30 mg (1)) and after the same dose on day 14 (ISDN 30 mg (14)). The response to sublingual GTN (GTN_{SL}) is shown. Values represent mean ± standard error of the mean (SEM). TWT was significantly prolonged over placebo ($p < 0.01$) at each testing time during acute therapy. During sustained therapy, only the 1-hour value was greater than the placebo value ($p < 0.01$).

The attenuated antianginal effects of ISDN have also been shown in a study with transdermal ISDN.[3] When active ISDN was initially applied, exercise time was prolonged for 8 hours. However, when applied once daily for 7 to 10 days, walking time was similar to that with placebo. Similarly, transdermal GTN patches increased treadmill walking time 2 and 4 hours after the initial application, but during once-daily application for 7 to 10 days, the effects were indistinguishable from placebo therapy.[4] These studies suggest tolerance to the antianginal effects of the nitrates during relatively short periods of regular therapy.

Although nitrate tolerance develops rapidly, there is evidence to suggest that tolerance is also rapidly reversible. We studied the blood pressure response to sublingual ISDN before and during short-term therapy with oral ISDN.[5] Attenuation of the hypotensive effect of sublingual ISDN occurred within 18 hours of initiation of oral ISDN therapy every 6 hours. Similarly, when oral ISDN was replaced with placebo, the normal hypotensive response to sublingual ISDN returned in less than 20 hours. The experimental design did not permit the assessment of the earliest time at which the reversal of this reduced effect occurred. Such rapid reversal of nitrate tolerance suggests that intermittent nitrate therapy might be preferable to the administration schedules that are designed to produce steady-state nitrate levels. Indeed, a recent study with once-daily therapy with sustained release oral ISDN reported no tolerance.[15]

The present study confirmed that 4-times-daily therapy with ISDN is associated with marked attenuation of its effects. Thus, walking time was prolonged for only 1 hour after a dose during sustained therapy. In contrast, buccal GTN administered 3 times daily was not associated with diminished clinical efficacy after 2 weeks of therapy. Is this difference related to differences between ISDN and GTN or to the different dosing schedule? No studies have been directed at the question of attenuated antianginal effects of GTN except for that of Reichek.[12] With GTN ointment in a group of 6 patients, he found no diminution of antianginal efficacy during sustained 3-times-daily application. If the present study had been carried out with similar dosing schedules, attenuated antianginal effects might have been seen with buccal GTN as well as with ISDN. Our current knowledge of the metabolism of the organic nitrates and the biochemical basis for their vasodilatation suggests that ISDN and GTN have similar mechanisms of action. Thus, it is unlikely that tolerance would develop to one of these agents and not the other, except through different dosing schedules.

With increasing evidence that 4-times-daily therapy with ISDN is associated with attenuation of hemodynamic and antianginal effects, dosing intervals must be studied. With the demonstration that relatively short nitrate-free periods are associated with the return of the normal hemodynamic effects of ISDN,[5] one could postulate that 4-times-daily therapy is not appropriate for the management of angina. Thus, perhaps oral nitrates should be given 2 or 3 times daily with a washout period to prevent the development of tolerance. This hypothesis is supported by the recent study from Germany, where once-daily oral therapy with a sustained-release form of ISDN showed no attenuation of antianginal efficacy.[15]

The development of tolerance to the antianginal effects of nitrates during 4-times-daily oral ISDN therapy, with long-acting ISDN cream and transdermal GTN patches raises important questions. Is it desirable to use nitrates in a manner in which therapeutic plasma levels are present throughout a 24-hour period? Apparently, intermittent therapy with a period of nitrate washout may be preferable and may prevent attenuation of the beneficial effects of the organic nitrates.

Once-a-day

MAXZIDE™

Triamterene **75 mg**/Hydrochlorothiazide **50 mg**/Lederle

THE FIRST AND ONLY REPLACEMENT FOR THE LESS BIOAVAILABLE TRIAMTERENE/ HYDROCHLOROTHIAZIDE FORMULATION... PROVEN SUPERIOR IN BIOAVAILABILITY

Please see last page of this advertisement for brief summary of prescribing information.

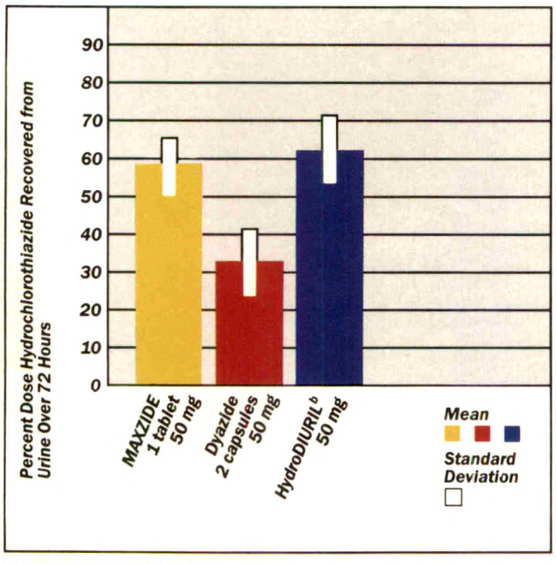
Once-a-day MAXZIDE™

Triamterene **75 mg**/Hydrochlorothiazide **50 mg**/Lederle

SUPERIOR DRUG DELIVERY AND ABSORPTION — TABLET TO TABLET, PATIENT TO PATIENT

MAXZIDE is optimally bioavailable and consistently delivers the prescribed dose of 75 mg triamterene and 50 mg hydrochlorothiazide. Dyazide®,* on the other hand, exhibits poor bioavailability. When given in equivalent doses, Dyazide delivers approximately half the amount of hydrochlorothiazide as MAXZIDE. Similarly, two Dyazide capsules deliver less than half the amount of triamterene as one MAXZIDE tablet.[1]

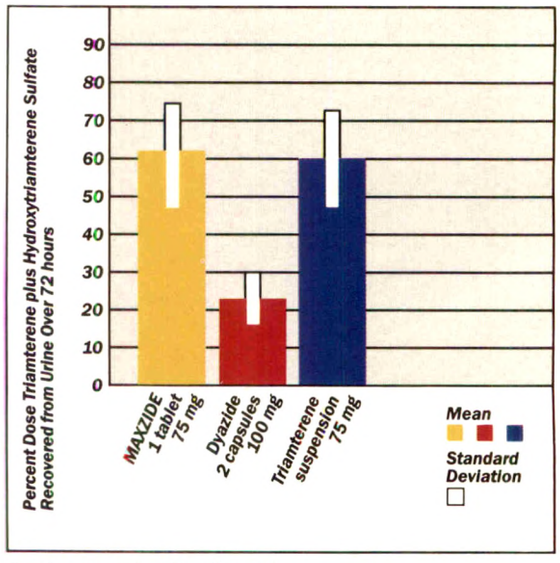
Percent dose of hydrochlorothiazide recovered from urine over 72 hours in subjects[a] given single oral doses



[a]Data from a study of 24 subjects.

[b]HydroDIURIL is the registered trademark of Merck & Co., Inc., for hydrochlorothiazide.

Percent dose of triamterene recovered from urine over 72 hours in subjects[a] given single oral doses



[a]Data from two studies of 24 subjects each.

DELIVERS THE PRESCRIBED DOSE ...
PROVIDES OPTIMAL ABSORPTION OF 75 MG TRIAMTERENE/ 50 MG HYDROCHLOROTHIAZIDE

A CLINICALLY SAFE AND EFFECTIVE ALTERNATIVE IN POTASSIUM-SPARING ANTIHYPERTENSIVE THERAPY

— **FOR PATIENTS ON HYDROCHLOROTHIAZIDE WHO DEVELOP HYPOKALEMIA**
— **FOR NEWLY DIAGNOSED PATIENTS IN WHOM THE DEVELOPMENT OF HYPOKALEMIA CANNOT BE RISKED**
— **FOR PATIENTS TRANSFERRED FROM DYAZIDE**

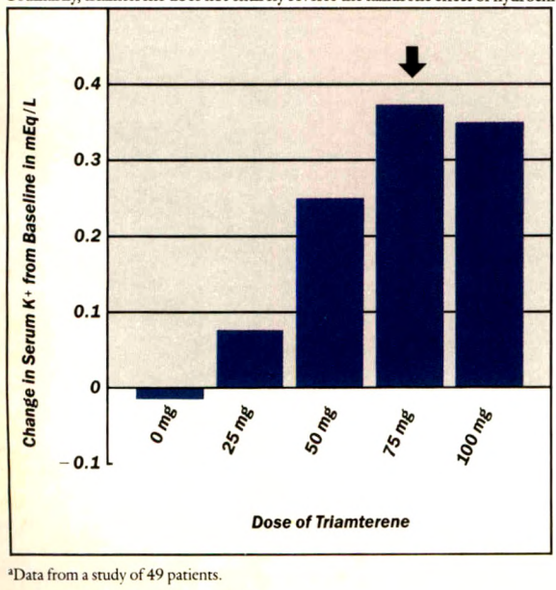
In a transfer safety study, patients taking up to four Dyazide capsules daily were effectively transferred to MAXZIDE q.d. with no compromise in clinical condition.[2]

PROVEN FORMULATION MAXIMIZES POTASSIUM-SPARING EFFECT OF TRIAMTERENE

In a clinical dose-response evaluation, 75 mg triamterene daily most successfully corrected the hypokalemic effect of repeated daily doses of 50 mg hydrochlorothiazide.[3†]

Dose-response evaluation of triamterene's potassium-sparing activity in patients[a] rendered hypokalemic with long-term daily doses of 50 mg hydrochlorothiazide

†Ordinarily, triamterene does not entirely reverse the kaliuretic effect of hydrochlorothiazide.



[a]Data from a study of 49 patients.

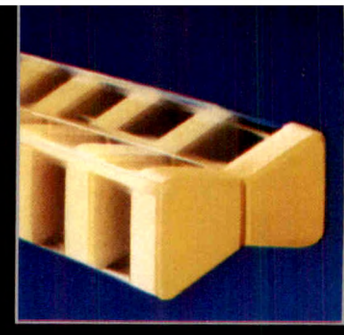
Once-a-day MAXZIDE™

Triamterene **75 mg**/Hydrochlorothiazide **50 mg**/Lederle



ECONOMICAL, ONCE-A-DAY POTASSIUM-SPARING ANTIHYPERTENSIVE THERAPY

BRIEF SUMMARY

Please see package insert for full prescribing information.

INDICATIONS AND USAGE: *MAXZIDE is indicated for the treatment of hypertension or edema in patients who develop hypokalemia on hydrochlorothiazide alone. It is also indicated for those patients who require a thiazide diuretic and in whom the development of hypokalemia cannot be risked (e.g., patients on digitalis preparations or with a history of cardiac arrhythmias, etc.).* ***This fixed combination drug is not indicated for the initial therapy of edema or hypertension except in individuals in whom the development of hypokalemia cannot be risked.*** *MAXZIDE may be used alone or in combination with other antihypertensive drugs such as beta-blockers. Since MAXZIDE may enhance the actions of these drugs, dosage adjustments may be necessary. Usage in Pregnancy: The routine use of diuretics in an otherwise healthy woman is inappropriate and exposes mother and fetus to unnecessary hazards. Diuretics do not prevent development of toxemia in pregnancy, and there is no satisfactory evidence that they are useful in the treatment of developed toxemia.*

CONTRAINDICATIONS: *Hyperkalemia: MAXZIDE should not be used in the presence of elevated serum potassium levels (greater than 5.5 mEq/liter). If hyperkalemia develops, this drug should be discontinued and a thiazide alone should be substituted. Concomitant use with other potassium conserving agents such as spironolactone, amiloride HCl or other formulations containing triamterene. Concomitant potassium supplementation in the form of medication, potassium-containing salt substitute or potassium-enriched diets should also not be used. Contraindicated in patients with anuria, acute and chronic renal insufficiency or significant renal impairment. Hypersensitivity to either component separately or other sulfonamide-derived drugs.*

WARNINGS: *Hyperkalemia.*

> *Abnormal elevation of serum potassium levels (greater than or equal to 5.5 mEq/liter) can occur with all potassium conserving agents including MAXZIDE. Hyperkalemia is more likely to occur in patients with renal impairment, diabetes (even without evidence of renal impairment), or elderly or severely ill patients. Since uncorrected hyperkalemia may be fatal, serum potassium levels must be monitored at frequent intervals especially in patients first receiving MAXZIDE, when dosages are changed, or with any illness that may influence renal function.*

If hyperkalemia is suspected, (warning signs include paresthesias, muscular weakness, fatigue, flaccid paralysis of the extremities, bradycardia and shock) an electrocardiogram (ECG) should be obtained. Monitor serum potassium levels because mild hyperkalemia may not be associated with ECG changes. If hyperkalemia is present, MAXZIDE should be discontinued immediately and a thiazide alone should be substituted. If the serum potassium level exceeds 6.5 mEq/liter, more vigorous therapy is required. The clinical situation dictates the procedures to be employed. These include the intravenous administration of calcium chloride solution, sodium bicarbonate solution and/or the oral or parenteral administration of glucose with a rapid acting insulin preparation. Cationic exchange resins such as sodium polystyrene sulfonate may be orally or rectally administered. Persistent hyperkalemia may require dialysis. The development of hyperkalemia associated with potassium-sparing diuretics is accentuated in the presence of renal impairment (see CONTRAINDICATIONS). Patients with mild renal functional impairment should not receive this drug without frequent and continued monitoring of serum electrolytes. Cumulative drug effects may be observed in patients with impaired renal function. The renal clearances of hydrochlorothiazide, the pharmacologically active metabolite of triamterene, and the sulfate ester of hydroxytriamterene have been shown to be reduced and the plasma levels increased following MAXZIDE administration to elderly patients and patients with impaired renal function. Hyperkalemia has been reported in diabetic patients with the use of potassium conserving agents even in the absence of apparent renal impairment. Avoid MAXZIDE in diabetic patients. If it is employed, serum electrolytes must be frequently monitored. Metabolic or Respiratory Acidosis: Potassium conserving therapy should also be avoided in severely ill patients in whom respiratory or metabolic acidosis may occur, since acidosis may be associated with rapid elevations in serum potassium levels. If MAXZIDE™ triamterene 75mg/hydrochlorothiazide 50mg is employed, frequent evaluations of acid/base balance and serum electrolytes are necessary.

PRECAUTIONS: *Electrolyte Imbalance and BUN Increases: Patients receiving MAXZIDE should be carefully monitored for fluid or electrolyte imbalances, i.e., hyponatremia, hypochloremic alkalosis, hypokalemia and hypomagnesemia. Serum and urine electrolyte determinations should be frequently performed and are especially important when the patient is vomiting or receiving parenteral fluids. Warning signs or symptoms of fluid and electrolyte imbalance include: dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia and gastrointestinal disturbances such as nausea and vomiting.*

Any chloride deficit during thiazide therapy is generally mild and usually does not require any specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather; appropriate therapy is water restriction, rather than administration of salt, except in rare instances when the hyponatremia is life threatening. In actual salt depletion, appropriate replacement is the therapy of choice.

Hypokalemia may develop with thiazide therapy, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids, ACTH, amphotericin B or after prolonged thiazide therapy. However, hypokalemia of this type is usually prevented by the triamterene component of MAXZIDE.

Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Hypokalemia can sensitize or exaggerate the response of the heart to the toxic effects of digitalis (e.g., increased ventricular irritability).

MAXZIDE may produce an elevated blood urea nitrogen level (BUN), creatinine level or both. This is probably not the result of renal toxicity but is secondary to a reversible reduction of the glomerular filtration rate or a depletion of the intravascular fluid volume. Periodic BUN and creatinine determinations should be made especially in elderly patients, patients with suspected or confirmed hepatic disease or renal insufficiencies. If azotemia increases, MAXZIDE should be discontinued.

Hepatic Coma: MAXZIDE should be used with caution in patients with impaired hepatic function or progressive liver disease, since minor alterations of fluid and electrolyte balance may precipitate hepatic coma. Renal Stones: Triamterene has been reported in renal stones in association with other calculus components. MAXZIDE should be used with caution in patients with histories of renal lithiasis. Folic Acid Deficiency: Triamterene is a weak folic acid antagonist and may contribute to the appearance of megaloblastosis in instances where folic acid stores are decreased. In such patients, periodic blood evaluations are recommended. Hyperuricemia: Hyperuricemia may occur or acute gout may be precipitated in certain patients receiving thiazide therapy. Metabolic and Endocrine Effects: The thiazides may decrease serum PBI levels without signs of thyroid disturbance.

Calcium excretion is decreased by thiazides. Pathological changes in the parathyroid gland with hypercalcemia and hypophosphatemia have been observed in a few patients on prolonged thiazide therapy. The common complications of hyperparathyroidism such as renal lithiasis, bone resorption, and peptic ulceration have not been seen. Thiazides should be discontinued before carrying out tests for parathyroid function.

Insulin requirements in diabetic patients may be increased, decreased or unchanged. Latent diabetes mellitus may become manifest during thiazide administration. Hypersensitivity: Sensitivity reactions to thiazides may occur in patients with or without a history of allergy or bronchial asthma.

Possible exacerbation or activation of systemic lupus erythematosus by thiazides has been reported. Drug Interactions: Thiazides may add to or potentiate the action of other antihypertensive drugs.

The thiazides may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. Thiazides have also been shown to increase responsiveness to tubocurarine.

Lithium, when given with diuretics, reduces renal clearance and increases the risk of lithium toxicity. Refer to the package insert for lithium before use of such concomitant therapy.

Acute renal failure has been reported in a few patients receiving indomethacin and other formulations containing triamterene and hydrochlorothiazide. Caution is therefore advised when administering nonsteroidal anti-inflammatory agents with MAXZIDE.

Drug/Laboratory Test Interactions: Triamterene and quinidine have similar fluorescence spectra; thus MAXZIDE may interfere with the measurement of quinidine.

Pregnancy: Category C: The safe use of MAXZIDE in pregnancy has not been established. Animal reproduction studies have not been conducted with MAXZIDE™ triamterene 75mg/hydrochlorothiazide 50mg. It is also not known if MAXZIDE can cause fetal harm when administered to a pregnant woman or can affect reproductive capacity. Thiazides cross the placental barrier and appear in cord blood. The use of thiazides in pregnant women requires that the anticipated benefit be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, pancreatitis, and possibly other adverse reactions which have occurred in the adult. MAXZIDE should be given to a pregnant woman only if clearly needed.

Nursing Mothers: Thiazides appear in breast milk. If the use of MAXZIDE is deemed essential, the patient should stop nursing. Pediatric Use: The safety and effectiveness of MAXZIDE in children has not been established.

ADVERSE REACTIONS: *Side effects observed in association with the use of MAXZIDE include drowsiness and fatigue, insomnia, muscle cramps and weakness, headache, nausea, appetite disturbance, vomiting, diarrhea, constipation, dizziness, decreased sexual performance, shortness of breath and chest pain, dry mouth, depression and anxiety. These adverse reactions are common to other triamterene and hydrochlorothiazide containing products. Other adverse reactions include:*

Hydrochlorothiazide:

Gastrointestinal: anorexia, gastric irritation, cramping, jaundice (intrahepatic cholestatic jaundice), pancreatitis, sialadenitis. Central Nervous System: vertigo, paresthesias, xanthopsia. Hematologic: leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia, hemolytic anemia, megaloblastosis. Cardiovascular: orthostatic hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Hypersensitivity: anaphylaxis, purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), fever, respiratory distress including pneumonitis. Other: hyperglycemia, glycosuria, hyperuricemia, restlessness, transient blurred vision.

Triamterene:

Hypersensitivity: anaphylaxis, photosensitivity and rash. Other: Triamterene has been reported in renal stones in association with other calculus materials. Triamterene has been associated with blood dyscrasias. Whenever adverse reactions are moderate to severe, therapy should be reduced or withdrawn.

DOSAGE AND ADMINISTRATION: *The recommended dosage of MAXZIDE is one tablet daily with appropriate monitoring of serum potassium levels (see WARNINGS). Patients receiving 50 mg of hydrochlorothiazide who become hypokalemic may be transferred to MAXZIDE directly. In patients requiring 50 mg of hydrochlorothiazide in whom hypokalemia cannot be risked, therapy may be initiated with MAXZIDE. There is no clinical experience with doses exceeding one tablet daily.*

Clinical studies have shown that patients already taking less bioavailable formulations of triamterene and hydrochlorothiazide (totaling 50-100 mg of hydrochlorothiazide and 100-200 mg of triamterene) may be safely changed to one MAXZIDE™ triamterene 75mg/hydrochlorothiazide 50mg tablet per day; these patients should be monitored clinically and with serum potassium after the transfer.

Collateral Flow in Patients with Acute Myocardial Infarction

WILLIAM D. NITZBERG, MD, HRUDAYA P. NATH, MD, WILLIAM J. ROGERS, MD, WILLIAM P. HOOD, Jr., MD, PATRICK L. WHITLOW, MD, RUSSELL REEVES, MD, and WILLIAM A. BAXLEY, MD

To assess the change in angiographically visualized collaterals in evolving acute myocardial infarction (AMI), coronary arteriograms from 53 patients obtained 6.2 ± 0.2 hours after onset of AMI symptoms were compared with follow-up angiograms obtained 14 ± 1 days later. Collaterals were graded according to intensity score and percent of distal infarct-related artery visualized. Collateral intensity score and the percent of distal infarct vessel visualized by collaterals at baseline were low, and there was a significant increase in both values at follow-up angiography. The group of 20 patients with occluded infarct vessels at follow-up study accounted for these increases. In 33 patients with patent infarct vessels at repeat angiography, collateral intensity score and percent of segment visualized were unchanged. Among the patients with occluded infarct vessels at baseline and subsequent improvement in left ventricular (LV) ejection fraction (EF), baseline collateral score and percent of segment visualized were significantly greater than in patients in whom LVEF did not improve. Thus, in patients with evolving AMI, (1) angiographically visible collaterals are not extensive within the early hours of AMI, (2) the extent of collaterals on follow-up angiography may not be representative of that on the day of AMI, (3) collaterals are considerably more common 2 weeks after AMI, especially in patients with occluded infarct arteries during follow-up, and (4) collaterals present at the time of AMI are associated with improved LVEF at 2 weeks.

(Am J Cardiol 1985;56:729–736)

Coronary artery collaterals are generally believed to be congenitally established channels whose further development and function are promoted by coronary stenosis and myocardial ischemic disease.[1,2] In previous studies collaterals have been examined relative to the circumstances in which they are present in chronic coronary artery disease[3,4] or after an AMI,[5] but only recently have investigators begun to examine their presence and role at the actual time of AMI. The trend toward increased utilization of emergency left-sided cardiac catheterization and coronary angiography, with acute reperfusion interventions such as streptokinase and balloon angioplasty, have provided the opportunity to study these vessels in the acute peri-infarction period.[6–10] The purpose of this study was to assess quantitatively the change in angiographically visualized collaterals in evolving AMI and to assess the relation between collaterals and subsequent improvement in left ventricular (LV) function.

Methods

Patients: Patients had undergone thrombolytic therapy for AMI in a study approved by the human research review committee in January 1982. Consenting patients with no contraindication to thrombolytic therapy or anticoagulation met the following criteria: (1) age 70 years or younger, (2) clinical presentation suggestive of evolving AMI, (3) electrocardiogram showing ST-segment elevation of 1.5 mm or more in 2 or more leads, or marked T-wave changes alone in an otherwise classic clinical presentation, (4) emergency catheterization including coronary angiography, left ventriculography and reperfusion intervention available within 12 hours of onset of pain, and (5) follow-up angiography performed within an average of 2 weeks later to assess patency of the infarct-related vessel and LV function.

Study design: After a brief medical history and physical examination had been obtained and the patient had given informed consent, all patients were premedicated with diphenhydramine, 50 mg intravenously i.v., and methylprednisolone, 1.0 g i.v. A No. 7Fr or 8Fr sidearm valved sheath was inserted into the right or left femoral artery and was sutured into place. Heparin, 5,000 IU i.v., was given. A pigtail ventriculography catheter was inserted, baseline LV pressure was recorded, and biplane left ventriculography was performed in the 20° cranial–60° left anterior oblique/45° right anterior oblique projections using 45 ml of diatrizoate sodium and diatrizoate meglumine (Renografin-76®) that was power-injected over 3 seconds.

Coronary arteriography of the suspected non–infarct-related artery was then performed, followed by injections in the infarct-related artery. Contrast was injected with enough force and quantity to give good visualization of the major coronary arteries and their tributaries. No specific attempt was made to opacify collaterals, which usually appeared late on the fluoroscopic screen, most often after cessation of contrast injection. Multiple views of the coronary arteries were routinely obtained: right coronary artery—left lateral, 60° left anterior oblique/15° cranial, and 30° right anterior oblique;

left coronary artery—60° left anterior oblique/15° cranial, left lateral, 30° right anterior oblique, 30° right anterior oblique/15° caudal, and 30° right anterior oblique/15° cranial. Angiograms were recorded on 35-mm film using a Phillips Polydiagnost-C movable C-arm, and were filmed in standard 6-inch mode. If total occlusion or high-grade stenosis of the infarct-related artery was found, the patient received 1 or more interventions, including intracoronary or intravenous streptokinase, with or without subsequent emergency percutaneous transluminal coronary angioplasty. No patient had emergency coronary artery bypass grafting. The details of reperfusion interventions and subsequent management are given elsewhere.[8] The diagnosis of myocardial infarction was confirmed by typical rise and fall of serial CK-MB isoenzyme levels. Left-sided cardiac catheterization with coronary and LV angiography was repeated in a similar fashion an average of 2 weeks later.

Coronary angiograms were viewed on a Tagarno 35 CX cine film analyzer. Coronary angiograms were reviewed by a cardiac radiologist. The baseline and follow-up angiograms were viewed in sequence, without prior knowledge of LV function. Angiographic global LV ejection fraction (EF) was derived by another uninvolved observer according to techniques previously described.[11]

Angiographic criteria for collaterals were direct visualization of accessory blood vesels either filling the distal segment of an occluded or severely stenotic artery or subserving the area of myocardium that would ordinarily be supplied by the severely stenotic vessel (intracoronary collaterals), or visualization of a coronary artery after injection of contrast material into the contralateral vessel (intercoronary collaterals).[2,12] Collaterals were graded according to the percent of distal infarct-related artery visualized by collaterals and by intensity.

The percent of distal infarct-related artery visualized by collaterals was determined in a semiquantitative fashion. Coronary artery segments were identified and categorized according to a modification of the nomenclature used in the Coronary Artery Surgery Study (CASS).[13] Figure 1 shows how the coronary arteries were separated into segments. When vessels or segments thereof were opacified on the cardiac silhouette on cine film, they were identified and quantitated visually based on comparison with CASS coronary artery segments as they would appear in similar roentgenographic projections. A schematic representation of this method is shown in Figure 2. Except for 25% and 75%, values were given to the nearest 10%.

Collateral intensity was scored from 0 to 4: grade 0 = no observed collateral opacification of the distal vessel; grade 1 = faint (questionable) opacification seen in only 1 angiographic projection; grade 2 = mild but definite opacification seen in 2 or more angiographic projections; grade 3 = moderate opacification readily observed but not equal in density to antegrade opacification; and grade 4 = rich opacification,

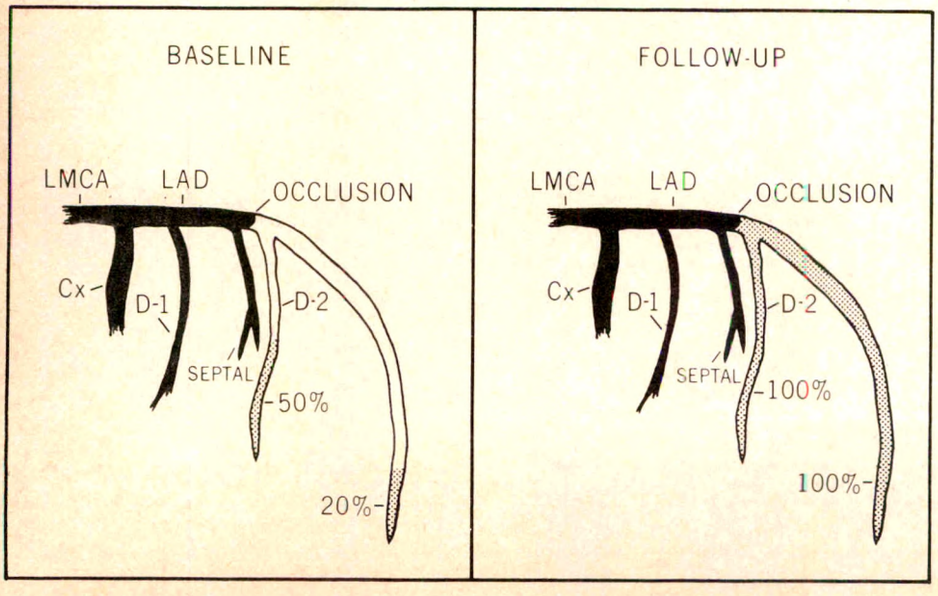

FIGURE 2. How the percent of infarct-related artery supplied by collaterals was determined. **Left,** initial angiogram reveals occlusion of the distal left anterior descending coronary artery (LAD). Twenty percent of the distal LAD and 50% of the second diagonal branch, (D-2) are opacified by collaterals. **Right,** at follow-up angiography, with persistent occlusion of the LAD, the entire distal LAD and the second diagonal branch are opacified by collaterals. Cx = left circumflex artery; LMCA = left main coronary artery.

equal to that which could be seen by anterograde flow. Figure 3 shows an example of intracoronary collaterals to the distal right coronary artery and its tributaries in 1 study patient on initial and repeat angiography.

Statistics: Data are reported as mean ± standard error of the mean. A paired or unpaired t test was used to assess the significance of difference between continuous variables. The chi-square test with Yates' continuity correction was used to assess the significance of differences between noncontinuous variables. The 2-sample Wilcoxon test was used for EF analysis.

Results

Patients: Fifty-three patients with AMI were admitted within 12 hours of onset of symptoms and satisfied the study criteria. Emergency coronary and LV angiography were performed within an average of 6 hours after onset of symptoms. All patients survived to follow-up angiography, which was performed an average of 14 days later. Patients were placed into 2 subgroups for analysis of data. Group 1 included 20 patients whose infarct-related artery was occluded at follow-up angiography. Group 2 included 33 patients whose infarct-related artery was patent at follow-up angiography. Baseline clinical and angiographic characteristics of the 2 groups were similar (Table I).

The mean age of the patients was 52 years on admission; most patients were men. Twelve patients in group 1 and 16 patients in group 2 had a history of angina (difference not significant [NS]). Five patients had a prior myocardial infarction (documented in 4 patients and undocumented in 1 patient), and all of these were in group 1 ($p < 0.01$). No patient had undergone prior coronary bypass surgery. There was a preponderance of 2-vessel coronary artery disease in group 1 and 1-vessel disease in group 2. The infarct-related artery was totally occluded at initial angiography in 87% (46 of 53) of the patients, and the 2 groups did not differ in this regard. No patient had a preintervention stenosis of less than 90% in the infarct-related artery at initial angiography. Of the 20 patients in group 1, 2 (10%) had subtotal and 18 (90%) had total occlusions at initial angiography. Of the 33 patients in group 2, 5 (15%) had subtotal and 28 (85%) had total occlusion at initial angiography. The infarct-related artery was usually the left anterior descending or right coronary artery. Hemodynamic measurements, including LV global EF and aortic and LV pressures, were similar between the 2 patient groups at both baseline and follow-up angiography. The interval from onset of symptoms to completion of initial angiography averaged 6.6 ± 0.5 hours in group 1 and 5.9 ± 0.2 hours in group 2 (NS).

Sixty-six percent (35 of 53) of patients had a successful reperfusion intervention, defined as restoration of patency to an initially occluded vessel, or a decrease in the initial stenosis in a subtotally occluded vessel. Successful reperfusion was seen in 8 patients in group 1 (40%) and 27 patients in group 2 (82%) ($p < 0.002$). Two patients in group 2 and none in group 1 had emergency percutaneous transluminal coronary angioplasty. All patients had CK-MB isoenzyme evidence of AMI.

The interval between initial and follow-up angiography averaged 16 ± 2 days (range 9 to 47) for group 1 patients and 13 ± 1 days (range 3 to 31) for group 2.

Presence of collaterals: Of the 53 patients in this study, 30 (57%) had angiographically visible collaterals at the initial catheterization during their evolving AMI. Of the 46 patients who initially had a totally occluded infarct-related artery, 26 (60%) had visible collaterals. Of the 7 patients with a subtotal occlusion at initial angiography, 4 (57%) had visible collaterals. Despite their presence, in many cases the extent of distal infarct-related vessel opacified by collaterals and the collateral intensity score were unimpressive.

Of the 20 patients in group 1, 12 (60%) had visible collaterals at baseline study, including the 2 patients with subtotal occlusions in their infarct-related artery. Eighteen patients (90%), including the 2 with initial subtotal occlusions, had an increase in extent or intensity of collaterals at the time of follow-up study. One patient had a decrease and 1 had no change in collaterals between the 2 studies. All 20 patients had some visible collaterals at follow-up angiography.

Of the 33 patients in group 2, 18 (55%) had some visible collaterals at initial angiography. These included 16 of the 28 patients (57%) who had completely occluded infarct-related arteries at baseline and 2 of the 5 patients (40%) whose infarct-related arteries were subto-

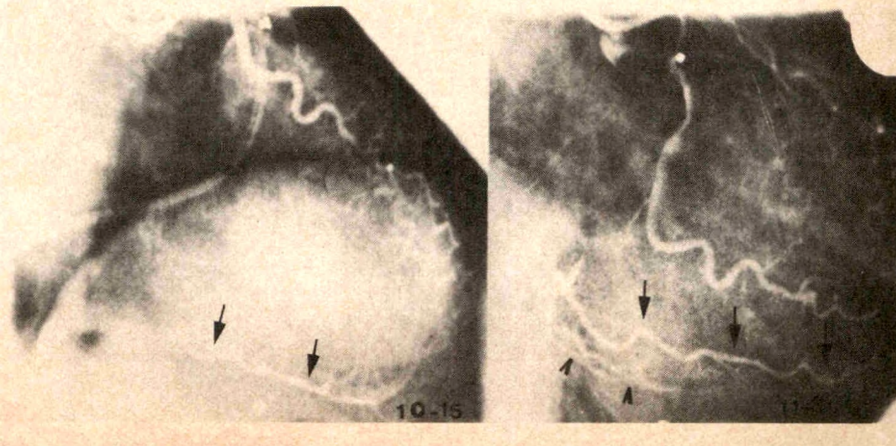

FIGURE 3. Left, right anterior oblique view of a left coronary arteriogram from the initial study of a patient with a right coronary artery occlusion. The **arrows** point to the posterior descending artery seen by intercoronary collaterals and graded with an intensity of 4. **Right,** at follow-up angiography 2 weeks later, the same view now shows, in addition to the posterior descending artery, the posterolateral segment artery, marked by **arrowheads** and also grade 4. The distal right coronary artery can also be seen just proximal to the origins of these branches and is graded as having an intensity of 3.

TABLE I Baseline Clinical and Angiographic Data

Variable	Infarct Artery Occluded at Follow-Up (n = 20)	Infarct Artery Patent at Follow-Up (n = 33)	p Value
Age (yr)	54 ± 2 (37–68)	51 ± 2 (33–70)	NS
Sex	15M/5F	29M/4F	NS
Prior angina	12 (60%)	16 (48%)	NS
Prior AMI	5 (25%)*	0	<0.01
Prior CABG	0	0	NS
Infarct related artery			
Totally occluded at baseline	18 (90%)	28 (85%)	NS
LAD	9 (45%)	16 (48%)	NS
LCx	4 (20%)	2 (6%)	NS
Right	7 (35%)	15 (45%)	NS
Extent of CAD (≥70% stenosis)			
1 vessel	7 (35%)	21 (64%)

* Four documented, 1 undocumented.

† EF data not available for 3 patients in group 2.

AMI = acute myocardial infarction; CABG = coronary artery bypass graft surgery; CAD = coronary artery disease; EF = ejection fraction; LAD = left anterior descending coronary artery; LCx = left circumflex coronary artery; LV = left ventricular; NA = not applicable; NS = not significant; PTCA = percutaneous transluminal coronary angioplasty.

tally occluded at baseline. In 1 of these latter 2 patients collateral intensity slightly increased and in 1 collaterals had disappeared by the time of repeat angiography. Of the 16 patients with collaterals and occluded infarct-related arteries at baseline, 13 (81%) had a decrease in extent or intensity of collaterals, 12 of whom had no visible collaterals, by the time of follow-up angiography. Of the remaining 3 patients, collateral extent and intensity were unchanged in 1 patient and increased in 2 patients between the 2 studies. These latter 2 patients were the only group 2 patients to have nearly total (99%) occlusions in their infarct-related artery at the time of follow-up angiography.

Quantitation of collaterals: *Collateral intensity score:* Figure 4 is a comparison of the mean collateral intensity score at baseline and follow-up angiography for the entire study group (n = 53) and for groups 1 (n = 20) and 2 (n = 33). The mean collateral intensity score for all patients was 0.5 ± 0.1 (range 0 to 4.0). This increased to 0.9 ± 0.2 (range 0 to 4.0) at follow-up angiography. Thus, overall, the mean collateral intensity score increased 0.5 ± 0.2 ($p < 0.02$). For group 1, the mean collateral intensity score was 0.6 ± 0.2 (range 0 to 4.0) at baseline and 2.2 ± 0.3 (range 0 to 4.0) at follow-up, or an increase of 1.6 ± 0.3 ($p < 0.0001$). For group 2 the mean collateral intensity score was 0.4 ± 0.8 (range 0 to 4.0) at baseline and 0.2 ± 0.1 (range 0 to 4.0) at follow-up, a decrease of 0.2 ± 0.8 (NS).

Percent of distal infarct-related artery visualized: Figure 5 is a comparison of the mean percent of distal infarct-related artery visualized at baseline and follow-up angiography. The mean percent of distal infarct-related artery visualized was 16 ± 4% (range 0 to 100%) for all patients at baseline study. This increased to 27 ± 5% (range 0 to 100%) at follow-up angiography, yielding a net increase of 12 ± 5% ($p < 0.04$). For group 1, the mean percent of distal infarct-related artery visualized was 20 ± 7% (range 0 to 100%) at initial angiography and 65 ± 7% (range 20 to 100%) at follow-up angiography, an increase of 45 ± 9% ($p < 0.0001$). For group 2, the mean percent of distal infarct-related artery visualized changed from 13 ± 4% (range 0 to 100) to 5 ± 3% (range 0 to 100) between the 2 angiographic studies, a decrease of 8 ± 4% ($p < 0.03$).

Relation between collaterals and left ventricular ejection fraction: LVEF data were not available for 3

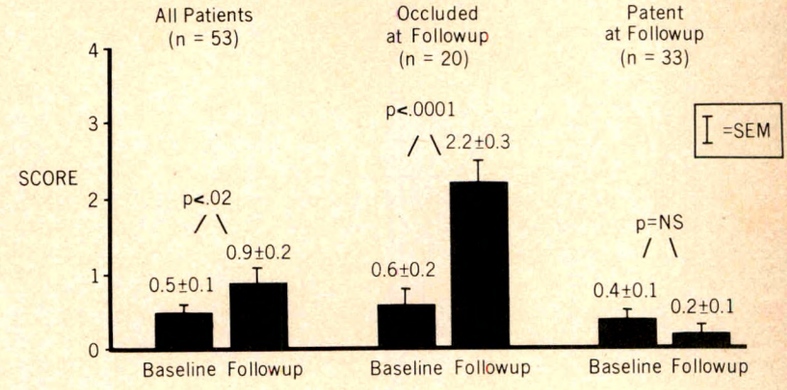

FIGURE 4. Comparison of the mean collateral intensity score at baseline and follow-up angiography for all 53 patients and for the 20 patients with occluded and the 33 patients with patent infarct-related arteries at repeat angiography. NS = not significant; SEM = standard error of the mean.

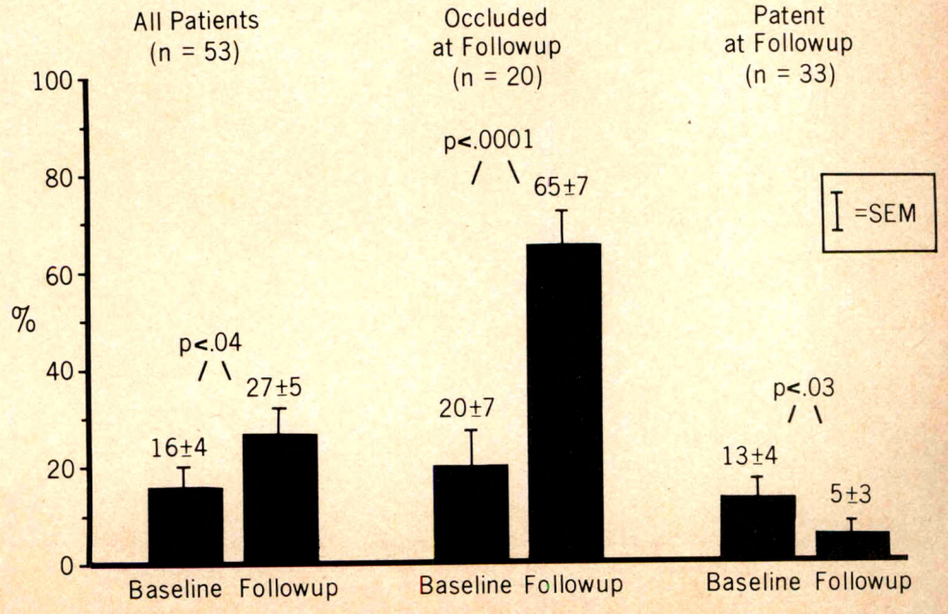

FIGURE 5. Comparison of the mean percent of distal infarct-related artery opacified at baseline and follow-up angiography for all 53 patients and for the 20 patients with occluded and the 33 patients with patent infarct-related arteries at repeat angiography. SEM = standard error of the mean.

patients in group 2 at initial angiography, but were available for all patients at follow-up. The mean global LVEF at baseline angiography was 50 ± 2% (range 31 to 65%) in group 1 and 46 ± 2% (range 27 to 69%) in group 2 (NS). The LVEF at follow-up angiography was 45 ± 2% (range 26 to 63) in group 1 and 49 ± 2% (range 29 to 70%) in group 2 (NS).

We observed a relation between the extent of collaterals present at baseline angiography and change in LVEF in the interval between initial and repeat angiography. In 46 patients the infarct-related vessels were totally occluded at baseline. LVEF data were available for 43 of these patients. In 15 of these patients LVEF subsequently increased (mean 10 ± 1%, range 1 to 19%), and in 28 it decreased or remained the same (mean −8 ± 1%, range 0 to 22%). Figure 6 is a comparison of the mean collateral intensity scores and the mean percent of distal infarct-related artery visualized at baseline angiography for each of these groups. At the time of initial angiography during AMI, the group whose LVEF subsequently increased had a higher mean collateral intensity score (0.8 ± 0.3, range 0 to 4.0) and mean percent of distal infarct-related artery visualized (32 ± 10%, range 0 to 100%) than did those whose LVEF subsequently failed to improve (0.2 ± 0.1, range 0 to 2.0), (7 ± 3%, range 0 to 80%). These differences in mean collateral intensity score and mean percent of distal infarct-related artery visualized were significant at the at the $p < 0.06$ and $p < 0.02$ levels, respectively.

Discussion

Several well-documented coronary collateral pathways are present in humans.[14] Coronary angiography can visualize collaterals of 100 μ or more and usually visualizes only epicardial vessels.[15] Humans have collaterals less than 100 μ in size, and most human collaterals are intramural or subendocardial.[1] Thus, the extent of collateral flow may not be represented by angiographic studies. However, collaterals may be inferred to be present by visualization of an obstructed coronary artery after contrast injection into a nonoccluded vessel or into the same, more proximally obstructed vessel, with no visible communication between the 2. For the purposes of this study, collaterals were considered present if they were visualized or if a portion of distal infarct-related artery was visualized.

The amount of contrast medium injected and duration of the cine run can affect the extent of collaterals seen, especially if contrast is injected specifically to view collaterals. In our study, contrast was injected with sufficient force and duration to opacify the major coronary arteries and their branches, then the cine run was continued until collaterals were well opacified or until it was clear that no collaterals were going to appear. No specific attempt was made to opacify collaterals by injecting with more force. Collaterals usually appeared later on the cine film, frequently at the very end of or after completion of contrast injection. Therefore, it is unlikely that any systematic bias toward better visualization of collaterals was introduced by the amount and rate of contrast injection. Although these factors may have affected collateral visualization, they should have done so in a uniform manner, and the trends in collateral formation and regression are unlikely to be an artifact of the contrast injection technique.

In this study 53 patients with AMI had coronary and LV angiography within a short time after onset of symptoms, and again an average of 2 weeks later. Fifty-seven percent of patients had angiographically visible collaterals to the infarct-related vessel at the time of AMI, and collaterals were seen with equal frequency in patients with total or subtotal occlusions as the cause of their AMI. This is a significantly higher percentage of patients than was reported in smaller series by Schwartz, Schuler and colleagues[9,10] of patients undergoing emergency coronary angiography during AMI, although these investigators did not recognize lower grades of collateral filling. The percentage with

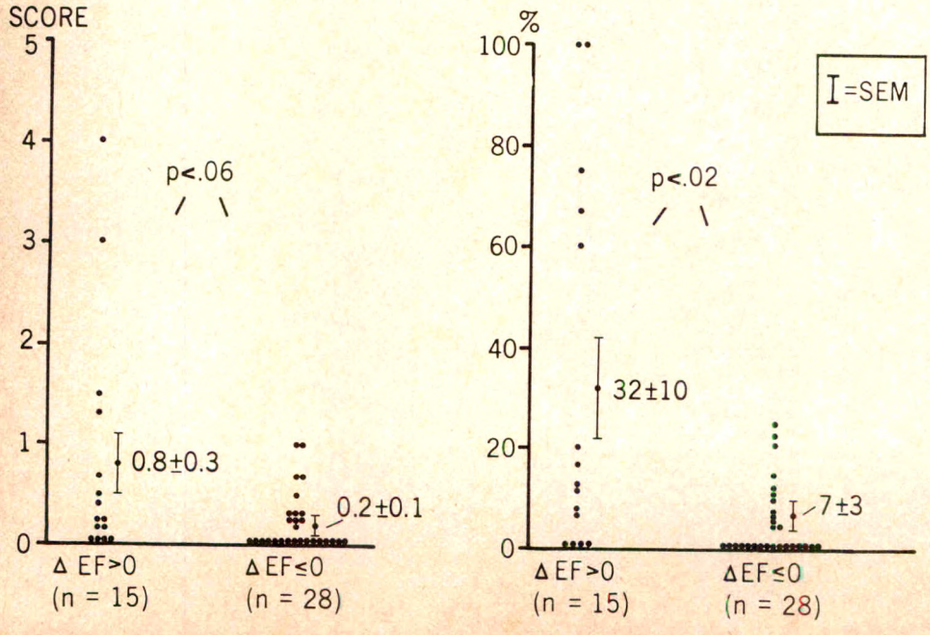

FIGURE 6. Comparison of the mean collateral intensity score (**left**) and the mean percent of distal infarct-related artery visualized by collaterals (**right**) at baseline angiography for the 15 patients in whom left ventricular ejection fraction (EF) improved (**left bar** in each graph) and for the group of 28 patients whose EF failed to improve (**right bar** in each graph) from baseline to follow-up angiography. SEM = standard error of the mean.

baseline collaterals in our study is similar to the figures reported by Rentrop et al.[6,7] In the more recent study by Rentrop's group, however, collateral status to the infarct zone is reported for only 46 of 55 patients who had both baseline and follow-up angiography, and this represented only one-fourth of all the patients in their series who initially had emergency coronary arteriography and were treated by streptokinase infusion.

In this study the extent and intensity of collaterals at baseline during AMI were generally low. The patency status at follow-up angiography had no relation to the degree of initial collateralization. The patency status at initial angiography had no bearing on the degree of collateralization at follow-up study. Rather, it was the presence of occlusion or high-grade stenosis at follow-up that was associated with improvement in the degree of collateralization by that time. Thus, collateral extent and intensity increased in patients whose infarct-related artery was occluded (group 1) or had very high grade stenosis (2 patients in group 2) 2 weeks after AMI.

The presence of increased collateral blood supply 2 weeks after AMI in patients with totally or subtotally occluded infarct-related vessels gives no information about when the increase occurred, nor does it explain what stimulated the increase. It is generally accepted that coronary collaterals are congenitally determined potential channels that do not function except in response to a pressure difference across or between coronary arteries as a result of obstruction or to myocardial ischemia per se,[16,17] or possibly other metabolic alterations.[7] When stimulated, collateral vessels develop thicker, more muscular walls and can function more like arterioles.[18] Experimental studies in dogs show that collateral channels develop over time to a point where they can be rapidly recruited to function maximally or not at all in response to transstenotic pressure gradients and tangential wall stress.[19,20] Similarly, studies in humans have shown the rapid appearance and regression of functioning collaterals after coronary artery bypass grafting and graft occlusion[21] or after development of a traumatic coronary artery fistula[22] or traumatic coronary artery occlusion.[23] Such observations suggest that collaterals in our patients increased after and in response to reocclusion or persistent occlusion of the infarct-related artery, although we do not know how rapidly this occurred or if the abruptness of reocclusion had any effect on extent of collateralization.

Collaterals and left ventricular function: At initial angiography there was no difference between group 1 and 2 in the degree of collateralization or LVEF, nor did LVEF differ at follow-up angiography. This is not surprising, as the amount of viable, functioning myocardium, dependent upon the extent of myocardial necrosis as well as preexisting ventricular function, is likely to be determined early in AMI.

Despite a relative paucity of collaterals at initial angiography, there was a relation between the degree of collateralization and subsequent improvement in LV function. Of the 46 patients with total occlusion of the infarct-related artery in the early hours of AMI, patients who had an increase in LVEF in the interval between studies tended to have more intense and more extensive collaterals than did those whose LVEF subsequently failed to improve. However, there was a good deal of variance in collaterals (Fig. 6). The group of 15 patients in whom EF improved included the 4 patients (27%) with the highest collateral intensity or percent of distal infarct-related artery visualized, but it also included 4 patients with no collaterals at baseline. In contrast, of the 28 patients in whom EF did not improve, 16 (57%) had no angiographically visbile collaterals early in the course of infarction.

The protective effect of collaterals on LV function is a major source of controversy. Pertinent to this study is the effects of collaterals on LVEF during the dynamic state of evolving AMI. Our data support the hypothesis that the degree of collateralization to the infarct-related coronary artery has a potential beneficial effect on subsequent improvement in LVEF, but that this is a variable effect. Multivariate analysis of the patients in this study shows that collaterals are one of several independent factors associated with improvement in LV function.[24] Other factors may include shorter time to reperfusion[10] and lower baseline EF.[24] Our findings are in agreement with those of Rentrop et al,[7] who reported a modest increase in EF after AMI in a group of patients with collaterals to the infarcting area before receiving streptokinase, but no change in the EF in a group lacking collaterals before streptokinase treatment.[7] In addition, their findings suggested that the critical interval for myocardial salvage and improvement in EF was longer in patients with well-developed collaterals. In a small series of patients, Schwartz et al[10] found that early reperfusion had a beneficial effect on late EF in association with the presence of collaterals, as well as a shorter duration of ischemia and smaller area of ischemic risk.

Limitations of the study: The patients in this study all received some reperfusion intervention. The persistence or regression of collaterals is not necessarily what would occur in a patient with evolving AMI who is not treated with such interventions. Although the endpoint (vessel patency) is the same, streptokinase or percutaneous transluminal coronary angioplasty may affect collaterals in ways apart from their effects on vessel patency and degree of stenosis, and the conclusions drawn from this study may not be valid in the natural history of evolving AMI.

Frequency and Significance of Induced Sustained Ventricular Tachycardia or Fibrillation Two Weeks After Acute Myocardial Infarction

ANIL K. BHANDARI, MD, JEFFREY S. ROSE, MD, ADAM KOTLEWSKI, MD, PhD, SHAHBUDIN H. RAHIMTOOLA, MB, FRCP, and DELON WU, MD

Electrophysiologic study, 24-hour ambulatory electrocardiographic monitoring, treadmill exercise test and angiographic evaluations were performed in 45 patients 14 ± 3 days (mean ± standard deviation) after acute myocardial infarction. Electrophysiologic study protocol included burst ventricular pacing and 1 to 3 ventricular extrastimuli at 2 cycle lengths from right ventricular apex, right ventricular outflow and left ventricle. Sustained monomorphic ventricular tachycardia (VT) (13 patients) or ventricular fibrillation (VF) (7 patients) was induced in 20 patients (44%) (group I). In these 20 patients, VT/VF was inducible with 2 extrastimuli in 10 patients, 3 extrastimuli in 9 patients and burst pacing in 1 patient. In the remaining 25 patients (56%), induction of no fewer than 7 ventricular beats were noted (group II). Severe left ventricular (LV) wall motion abnormalities occurred in 70% of group I patients and 22% of group II patients ($p < 0.005$). There was no difference in the site of infarction, frequency and grade of ventricular ectopic rhythm on ambulatory electrocardiographic monitoring, double product on submaximal exercise, LV ejection fraction, and number of obstructed coronary arteries (70% or greater) ($p > 0.1$) between group I and group II patients. During a mean follow-up of 10 ± 3 months, 1 patient in each group died suddenly, and in 1 group I patient spontaneous sustained VT developed which was identical in morphologic configuration to that induced during electrophysiologic study.

In conclusion, electrical induction of sustained VT or VF during electrophysiologic study is common in patients 2 weeks after acute myocardial infarction. These patients have an increased incidence of LV wall motion abnormalities. The prognostic significance of this finding requires further follow-up study but appears to be of limited value.

(Am J Cardiol 1985;56:737–742)

Patients discharged from the hospital after an acute episode of myocardial infarction (MI) are at an increased risk of death particularly during the first year after this event.[1–6] The presence of left ventricular (LV) dysfunction, frequent and complex ventricular ectopic rhythms on ambulatory electrocardiographic monitoring, and myocardial ischemia or angina during low-level treadmill testing identifies a high-risk subgroup among these patients.[1–5,7–9] However, these variables lack sensitivity and specificity and may not warrant specific intervention in a given patient.[5]

Electrophysiologic studies have been shown to be useful in the management of patients with ventricular tachycardia (VT) and patients with out-of-hospital cardiac arrest due to ventricular fibrillation (VF).[10–13] Preliminary studies by Hamer et al[14] and Richards et al[15] in patients with acute MI suggested that programmed ventricular stimulation may be useful in identifying a subgroup of patients at high risk of sudden cardiac death. Therefore, we prospectively performed electrophysiologic, ambulatory electrocardiographic, exercise treadmill and angiographic studies in patients with acute MI in order to evaluate the relation between the response to programmed stimulation and the angiographic and other findings; and to determine the usefulness of programmed ventricular stimulation as a marker for the development of subsequent VT or sudden death.

Methods

Patients: From September 1983 to July 1984, 102 patients were admitted to the coronary care unit of Los Angeles County–University of Southern California Medical Center with a confirmed diagnosis of acute MI. Eighty-four of them had transmural infarction and were considered for inclusion in the study. Criteria for transmural infarction were: ischemic chest pain lasting longer than 30 minutes, characteristic rise and fall of the serum CK level and its MB isoenzyme fraction, and characteristic evolutionary ST-T changes with the de-

velopment of new q waves over 2 or more frontal or precordial leads. There were 9 inhospital deaths. Thirty patients were excluded: 9 because of the presence of unstable angina or uncontrolled heart failure in the postinfarction period; 2 because they were older than 70 years; 7 because of end-stage disease of other organ system; and 12 because of refusal to have the studies performed. The remaining 45 patients agreed to have the studies performed and form the basis of this report. There were 41 men and 4 women, aged 35 to 67 years (mean standard deviation 52 ± 9). Twenty-two patients had anterior and 23 had inferior MI. Peak CK was 2,003 ± 1,552 units with an MB isoenzyme fraction of 16 ± 9% (normal, less than 5%). Thirteen patients had mild congestive heart failure (New York Heart Association class I or II) and 10 had mild angina after infarction. Except for 3 patients in whom primary VF developed during the first 24 hours of hospitalization, none had sustained VT or VF before the study.

The studies were performed 9 to 21 days after infarction and consisted of (1) 24-hour ambulatory electrocardiographic monitoring, (2) low-level treadmill exercise test, (3) programmed ventricular stimulation and (4) cardiac catheterization with coronary angiography. The last 2 studies were done on the same day. The longest interval between all 4 tests were never more than 7 days. Each patient gave informed consent. None of the 45 patients received antiarrhythmic agents or β-blocking drugs at the time of study. Nitrates (37 patients), digoxin (5 patients), diuretic drugs (13 patients) and calcium blockers (6 patients) were discontinued 24 hours before programmed ventricular stimulation. On the day of the study, the serum potassium level was normal (range 3.5 to 5.2 mEq/liter) in all patients, and the serum digoxin level ranged from 0.7 to 1.2 ng/ml in those taking digoxin.

Programmed ventricular stimulation: Programmed ventricular stimulation was performed with patients in the fasting and nonsedated state. A No. 6 quadripolar electrode catheter was introduced percutaneously into the right femoral vein and was first positioned at the right ventricular (RV) apex and then the RV outflow tract for stimulation. If necessary, a second No. 6 Fr electrocatheter was introduced percutaneously into the right femoral artery and advanced to the LV apex for LV stimulation. Surface electrocardiographic leads V_1, I and aVF, as well as RV and LV electrograms, were stimultaneously displayed and recorded on an oscilloscopic photographic recorder (Electronics for Medicine, VR-16) at speeds of 25 to 100 mm/s. Stimuli 2 ms in duration and twice the diastolic threshold were provided by a digital programmable stimulator (Bloom & Associates, Ltd). The stimulation protocol included burst ventricular pacing between cycle lengths of 400 to 250 ms, and single (S_1S_2), double ($S_1S_2S_3$) and triple ($S_1S_2S_3S_4$) extrastimuli at 2 driven cycle lengths of 500 and 400 ms. In all patients stimulation was begun at the RV apex with burst pacing and was followed by single and then double extrastimuli. If sustained VT or VF was not induced, the same stimulation sequence was applied to the RV outflow tract and then to the LV apex. When double extrastimuli failed to induce sustained VT or VF, a third ventricular extrastimuli was added and the same stimulation protocol was repeated at all 3 sites. The study was terminated when sustained VT or VF was induced, and was usually completed within 20 minutes.

Sustained VT was defined as VT that lasted longer than 30 seconds or that caused hemodynamic compromise requiring termination by overdrive pacing or cardioversion in less than 30 seconds.[10–13] *Nonsustained VT* was VT that lasted from 6 beats to 30 seconds and terminated spontaneously. *VF* was defined as organized or disorganized ventricular activity with a cycle length of less than 200 ms requiring immediate defibrillation.

Cardiac catheterization and coronary angiography: Right- and left-sided cardiac catheterization and LV and coronary angiography were performed after programmed ventricular stimulation. Pressures were recorded using Statham P23Db transducers and cardiac output was determined by the thermodilution technique. LV angiograms were performed in the 30° right anterior oblique (44 patients) and 55° left anterior oblique projections (43 patients), while coronary anteriograms were taken in multiple views using 35-mm cineangiography (44 patients). In 1 patient, LV catheterization and coronary angiography could not be performed because of technical difficulty in negotiating the catheter across the tortuous iliac artery system.

LV end-diastolic and end-systolic volumes and ejection fraction were calculated from the right anterior oblique projection using the area-length method.[16] Both LV and coronary angiograms were evaluated by 2 of us. If disagreement occurred, the film was reviewed by a third observer to obtain a consensus. The criterion for a "significant" stenosis was 70% or more reduction in internal diameter of these vessels. For the left main coronary artery, a 50% or greater reduction in internal diameter was considered significant. The circumflex artery was considered involved if its main vessel or the large obtuse marginal branch was stenotic. Stenoses involving only the branches of left anterior descending or right coronary arteries was not counted. Left main stenosis was classified as 2-vessel disease. No major vessel was counted twice.

The LV angiograms were analyzed for wall motion in *both* right anterior oblique and left anterior oblique projections (43 patients) using the method previously described.[17] Each projection was divided into 5 equal segments and a quantitative wall motion score was determined from the analysis of 10 segments. The contraction of each segment was scored as follows: normal = 1, moderate hypokinesia = 2, severe hypokinesia = 3, akinesia = 4, and dyskinesia = 5.[17] The total score was obtained by adding the values assigned to each segment. With this system, a score of 10 equals normal wall motion function, 10 to 15 indicates a mild motion abnormality, 15 to 25 a moderate wall motion abnormality, and more than 25 severe wall motion abnormality.

Ambulatory electrocardiographic monitoring: All patients underwent 24-hour continuous ambulatory electrocardiographic monitoring 6 to 17 (mean 10 ± 3) days after infarction. Two-channel high-fidelity cassette recordings were analyzed for frequency, morphologic characteristics and timing of premature ventricular complexes using a Del Mar Avionics system.

Treadmill exercise test: Thirty-five patients underwent a low-level treadmill exercise test according to a modified Sheffield's protocol 7 to 14 days (mean 10 ± 2) after infarction. The exercise was continued until a target heart rate of 120 beats/min was achieved or the patient had angina, 0.2 mV horizontal or downsloping ST-segment depression, marked fatigue, high-grade ventricular ectopy or systolic hypotension of 20 mm Hg or more. A result was considered positive when any recorded lead during exercise or during recovery showed a horizontal or downsloping ST-segment depression of 0.1 mV or more at 80 ms after the J point.

Follow-up study: Patients were followed in the cardiology clinics of the Los Angeles County-University of Southern California Medical Center at intervals of 4 to 8 weeks; some were followed by their private physicians. If a patient died, the circumstance of the event was determined. Sudden death was defined as death that occurred within 1 hour after the onset of terminal symptoms or when death occurred unexpectedly without premonitory symptoms.

Statistical analysis: Values are expressed as mean ± standard deviation. Patients with and without induction of

sustained VT or VF were compared using a chi-square test or Student *t* test. The difference was considered statistically significant when the p values were ≤0.05 and not statistically significant when the p value was >0.1. The p values between 0.05 and 0.1 are given.

Results

Induction of ventricular tachycardia or ventricular fibrillation: Programmed ventricular stimulation induced sustained monomorphic VT in 13 patients and polymorphic VT that degenerated into VF in 7 patients. Thus, 20 of the 45 patients (44%) (group I) had induction of sustained VT or VF. In 13 patients with induction of sustained monomorphic VT, the QRS morphologic pattern was of right bundle branch block pattern in 9 and a left bundle branch pattern in 4; the cycle length ranged from 200 to 270 ms (mean 228 ± 23). VT could be terminated by overdrive pacing in 6 patients and required cardioversion in 7. All 7 patients with induction of polymorphic VT that degenerated into VF required immediate direct-current cardiac shock. Sustained VT or VF was induced from the right ventricle in 15 patients and the left ventricle in 5. It was induced by burst pacing in 1 patient, double ventricular extrastimuli in 10 patients and triple ventricular extrastimuli in 9 patients.

Of the remaining 25 patients (group II), 1 had induction of nonsustained monomorphic VT lasting for a maximum of 7 beats; the induction required double extrastimuli at the RV apex. Five patients had induction of repetitive ventricular responses of maximum 3 to 5 beats with triple extrastimuli, and 19 patients had induction of no ventricular responses during the study.

Comparison of patients with and without induction of sustained ventricular tachycardia or ventricular fibrillation: Group I patients had higher levels of serum CK and increased incidence of heart failure (Table I). The mean interval between infarction and programmed ventricular stimulation was longer in group I than in group II (15 ± 3 vs 13 ± 3 days, p <0.05). There were no significant differences between the 2 groups in the mean frequency or incidence of repetitive forms of ventricular premature complexes detected during 24-hour ambulatory monitoring (Fig. 1). Two groups did not differ significantly with regard to the findings on treadmill testing (Table I), angiographic LV ejection fraction (0.45 ± 0.1 vs 0.50 ± 0.1, p >0.1), LV end-diastolic pressure (24 ± 8 vs 24 ± 9 mm Hg) and LV stroke work index (41 ± 17 vs 48 ± 14 g-m/m^2).

Mean LV wall motion score was significantly higher in group I than in group II, 22 ± 6 vs 17 ± 5 (p <0.005) (Table II). Fourteen of the 20 patients (70%) with inducible sustained VT or VF (group I) had moderate to severe wall motion abnormalities with a wall motion score of at least 20, compared with 5 of the 23 patients (22%) without inducible VT or VF (group II) (p <0.005). Group I patients also had a significantly higher inci-

dence of LV aneurysms than group II patients (45 vs 13%, p <0.05) (Fig. 2). Coronary angiography showed that 14 patients (32%) had 1-vessel disease, 14 (32%) had 2-vessel and 15 (34%) had 3-vessel disease. In 1 patient, the coronary arteries were normal. Twenty-three of the 44 patients (52%) had complete occlusion of at least 1 major vessel. There was no significant difference in the number or distribution of diseased vessels between the 2 groups. Main left coronary artery stenosis was observed in only 1 patient, who was in group II.

Treatment and follow-up observations: Of the 13 group I patients with inducible sustained monomorphic VT, 10 underwent electropharmacologic testing with intravenously administered procainamide (loading dose: 15 mg/kg body weight followed by a constant infusion at 2 mg/min). Although procainamide prevented induction of VT (more than 6 beats) in only 3 patients, all 10 were discharged with oral procainamide 3 to 4 g/day. This therapy, however, was discontinued 2 to 3 months after discharge in all except 2 patients, who have been maintained with procainamide treatment at the discretion of their attending physicians. All other patients were discharged from the hospital without any specific antiarrhythmic therapy. None of the 45 patients received a β-blocking agent. Two patients in each group underwent coronary bypass surgery for either left main coronary disease (1 patient) or persistent angina refractory to medical therapy (3 patients).

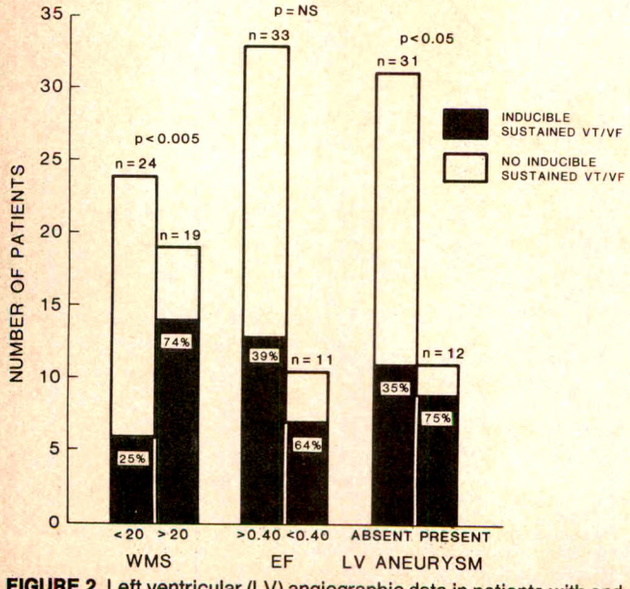

FIGURE 2. Left ventricular (LV) angiographic data in patients with and without inducible sustained ventricular tachycardia (VT) or ventricular fibrillation (VF). EF = ejection fraction; NS = not significant; WM = wall motion score.

The follow-up of these 45 patients ranged from 4 to 17 months (mean 10 ± 3). Thirty-six were followed in the Cardiology Clinic of Los Angeles County–University of Southern California Medical Center, and in 7 patients the follow-up data were obtained by telephone from their referring physicians (2 patients), the patients themselves (3 patients) or their family (2 patients). Two patients in group II were lost to follow-up 4 and 5 months, respectively, after discharge from the hospital. During the follow-up period 2 patients died suddenly; 1 had inducible sustained VT (group I) and the other had induction of no more than 5 repetitive beats (group II). Sudden death occurred 17 and 2 months, respectively, after the index MI, and at the time of its occurrence both patients were taking no antiarrhythmic agents. One group I patient had spontaneous sustained VT (nonfatal) 25 days after the index MI. This VT was identical in morphologic pattern to the one induced during programmed ventricular stimulation. There have been 2 nonsudden deaths; 1 group I patient died from intractable cardiac failure 10 months after the index infarction and 1 group II patient who was asymptomatic and taking no specific therapy had a suicidal death 72 days after the initial infarction. The remaining 38 patients were still alive and have had no documented occurrence of sustained VT/VF during a follow-up of 8 to 17 months (mean 12 ± 4). Two patients (group I) have had recurrent episodes of heart failure and 1 patient (group I) sustained an uncomplicated subendocardial infarction 3 months after the index infarction.

Discussion

The survivors of acute MI after discharge from the hospital are at increased risk of death during the first year after their event, with an average mortality rate of 7 to 11%.[1–6] Sudden cardiac death accounts for half of these deaths and is usually a result of VT or VF. Programmed ventricular stimulation has been shown to be useful in the diagnosis and management of patients with recurrent sustained VT or out-of-hospital cardiac arrest.[10–13] Therefore, one may hypothesize that programmed ventricular stimulation would be helpful in predicting patients at high risk of sudden death in the first year after MI, and preliminary data by Hamer et al[14] and Richards et al[15] appear to confirm this. Hamer et al studied 70 patients with recent MI complicated by heart failure or arrhythmias or both. They found that induction of 5 or more repetitive ventricular responses identified a high-risk subgroup of 12 patients, of whom 4 died suddenly during a 12-month follow-up period. However, 5 of their remaining 58 patients without induction of 5 or more repetitive ventricular responses also died suddenly during follow-up. Thus, they had studied selected patients and their findings had low specificity. Richards et al studied 165 hemodynamically stable patients 6 to 28 days (mean 10) after MI. Of the

38 patients with induction of VT lasting longer than 10 seconds, 8 died suddenly during a mean follow-up period of 8 months, whereas none of the remaining 127 patients without induction of VT encountered sudden death. In contrast, Marchlinski et al[18] studied 46 patients with recent infarction and found that only 1 of the 10 patients with induction of sustained or nonsustained VT died suddenly during a mean follow-up period of 18 months, whereas 5 of the remaining 36 patients without induction of VT died suddenly.[18] These conflicting results may be a result of significant differences in patient selection, protocols for stimulation during the electrophysiologic study and definition of positive responses. Moreover, none of these studies correlated the induction of VT or VF with the severity of coronary artery disease, hemodynamic or angiographic parameters.

In the present study, we excluded patients with uncontrolled heart failure or unstable angina because such patients are at high risk, and the patients with unstable angina have an excellent response to coronary bypass surgery.[19–21] A vigorous stimulation protocol was used that consisted of triple ventricular extrastimuli from both the right and left ventricles. Programmed stimulation using this protocol has been reported to induce clinical arrhythmias in 80 to 98% of the patients who present with recurrent sustained VT or cardiac arrest.[10,11,22] Also, in patients without documented ventricular arrhythmias, sustained VT is almost never induced and the induction of VF is infrequent.[22–24] Two weeks after MI, we could induce sustained VT or VF in 22% of patients with double extrastimuli and in 44% with triple extrastimuli. The patients in whom sustained VT or VF was induced had more severe wall motion abnormalities, had an increased incidence of mild heart failure and LV aneurysms and tended to have lower LV ejection fractions and larger infarcts judged by peak CK values. These findings are in accord with previous observations made in the survivors of out-of-hospital cardiac arrest in whom the presence of moderate to severe LV wall motion abnormalities was associated with more frequent induction of VT or VF,[25] as well as an increased incidence of recurrent cardiac arrest.[26] Our findings are also in accord with canine ischemic models in which electrical instability occurred more often with a large infarct.[27]

The relatively short term follow-up and the small number of patients in our study do not permit us to determine whether programmed ventricular stimulation identifies patients after infarction who are at high risk of sudden death. However, the inducibility of sustained VT/VF 14 ± 3 days after acute MI did not appear to have clinical significance during the mean follow-up of 10 ± 3 months. Whereas 44% of the patients had inducible sustained VT or VF, only 1 had spontaneous sustained VT and 1 died suddenly during the follow-up period. The other sudden death occurred in a patient who had no inducible VT. The study raises an important question as to the clinical significance of inducible sustained VT or VF during the early period after infarction. In a study of 40 patients with sustained VT that occurred within 2 months after infarction, Marchlinski et al[28] induced nonclinical forms of sustained VT in 45% of patients. Kowey et al[29] induced sustained VT in 5 of 57 asymptomatic patients (9%) with recent infarction; 4 were studied within 3 months of infarction. Buxton et al[30] studied a group of 33 patients with stable coronary artery disease and nonsustained VT; 13 (40%) had induction of sustained VT or VF. Recent MI may provide an anatomic substance for induction of VT or VF that has little long-term clinical significance. These questions must be answered by additional studies, because the inducibility of sustained VT or VF may decline 3 to 6 months after infarction; however, the high incidence of sudden death also declines 6 months after MI.

Ten of the 20 patients with inducible sustained VT/VF (group I) received antiarrhythmic therapy. This therapy may have influenced the subsequent posthospital course of these patients. However, this is less likely because acutely administered procainamide in the laboratory failed to suppress induction of VT in most of these patients, and antiarrhythmic therapy was discontinued 2 to 3 months after the index infarction in almost all of them. Moreover, there are no data that indicate a beneficial effect of antiarrhythmic therapy on the survival of patients after MI.

Crossover from Intravenous to Transdermal Nitroglycerin Therapy in Unstable Angina Pectoris

SHU-GUANG LIN, MD, and JOHN T. FLAHERTY, MD

The present study was designed to examine the safety and efficacy of titrating a nitroglycerin infusion to a fixed hemodynamic endpoint as initial therapy for patients admitted to a coronary care unit for medically refractory unstable angina, and to test the hypothesis that patients, responding to the addition of intravenous (i.v.) nitroglycerin to their previous antianginal regimen, could be crossed over to nitroglycerin administered by a new transdermal delivery system. In 9 patients the nitroglycerin infusion titrated upward at 3- to 10-minute intervals until a 10% reduction in mean arterial pressure was achieved. This titration schedule and hemodynamic endpoint proved safe and effective for controlling episodes of chest pain at rest in all 9 patients. Subsequently, this treatment strategy was tested in 17 consecutive patients with unstable angina treated in our coronary care unit during a 1-month period. In 10 of 15 successfully treated patients ischemia was the cause of chest pain as documented by cardiac catheterization. No change was made in antianginal or vasoactive drugs during the period of i.v. nitroglycerin administration or during crossover to transdermal therapy. In this well defined subgroup of patients with unstable angina, nitroglycerin infusion decreased the mean arterial pressure from 101 ± 18 to 87 ± 11 mm Hg (mean ± standard deviation), using an infusion rate of 84 ± 74 μg/min (range 10 to 200). The mean duration of i.v. therapy was 36 ± 12 hours. In 4.8 ± 0.9 hours, all 10 patients were weaned off i.v. therapy and crossed over in a stepwise fashion to a mean dose of 22.5 ± 10 mg/24 hours of transdermal nitroglycerin patches (range 5 to 40 mg/24 hours), while maintaining the mean arterial pressure reduction previously achieved after initiation of i.v. therapy. Mean arterial pressure was 86 ± 11 mm Hg with i.v. therapy immediately before crossover and was maintained at 83 ± 9 and 85 ± 11 mm Hg 1 and 24 hours after crossover to transdermal nitroglycerin therapy, respectively. Two patients had episodes of chest pain during the first 24 hours of transdermal therapy. Both became pain free after upward titration of the transdermal dose by 10 mg/24 hours. Among these 10 patients, 7 had no further episodes of pain throughout the remainder of their hospitalization. One patient had a single episode of chest pain after transient interruption of transdermal nitroglycerin therapy and 1 patient had a single episode of pain after transient reduction in the transdermal dose. These results suggest that i.v. nitroglycerin, titrated to reduce mean arterial pressure by 10% is safe and effective treatment for patients with unstable angina admitted to a coronary care unit, and that the new transdermal nitroglycerin delivery systems can be used successfully to maintain the beneficial antiischemic effects initially achieved with i.v. nitroglycerin therapy.

Sublingual nitroglycerin has been successfully used to treat episodes of angina pectoris for more than 100 years.[1] Although the use of intravenous (i.v.) nitroglycerin was first reported more than 20 years ago,[2] it was only released for clinical use by the Food and Drug Administration in October 1981. Subsequently, several

studies have demonstrated beneficial effects of adding i.v. nitroglycerin to prior medical therapy in patients admitted to a coronary care unit with the diagnosis of unstable angina.[3–5] If episodes of chest pain at rest are brought under control with i.v. nitroglycerin therapy, and if one wishes to continue nitrate therapy, it would be necessary to switch to a route of administration that could be continued on a regular medical floor and then on an outpatient basis. Sublingual, buccal, oral and topical nitrate preparations with durations of action of 1½ to 6 hours are available. However, all require multidose administration for continuous prophylactic therapy. Recently, transdermal delivery systems have been developed that propose to deliver nitroglycerin continuously for 24 hours.[6]

The present study has 2 parts. The first part is a prospective study that tested the hypothesis that a 10% reduction in mean arterial pressure is a safe and effective initial endpoint for the titration of i.v. nitroglycerin in patients with unstable angina. The second part is a retrospective study that tested the therapeutic strategy of adding i.v. nitroglycerin to prior medical therapy and also tested the hypothesis that patients whose unstable angina is controlled after the addition of i.v. nitroglycerin could be crossed over to transdermal nitroglycerin with continued control of their episodes of chest pain at rest.

Methods

Patient groups: *Prospective study:* Nine nonconsecutive patients admitted to The Johns Hopkins Hospital Coronary Care Unit with the diagnosis of unstable angina were entered into the prospective study, which tested the safety and efficacy of a 10% reduction in mean arterial pressure as the initial titration endpoint for i.v. nitroglycerin therapy (Table I). The study group consisted of patients who had had 1 or more episodes of chest pain at rest associated with at least 1 mm of ST-segment elevation or depression during the 12 hours before initiation of the nitroglycerin infusion. Patients were selected by daytime presentation and availability of the research nurse. Exclusion criteria included: (1) systolic blood pressure less than 100 mm Hg, (2) severe liver or renal disease, (3) suspected increased intracranial or intraocular pressure, and (4) constrictive pericarditis or pericardial tamponade.

All 9 patients had obtained relief of their last chest pain episode with 1 or more 0.4-mg sublingual nitroglycerin tablets. Seven of 9 patients were taking long-acting nitrates, 3 were taking β blockers and 4 were taking calcium channel blockers before admission to the coronary care unit (Table II). Cardiac catheterization was performed in 8 of 9 patients (Table I).

Retrospective study: Seventeen consecutive patients were admitted to The Johns Hopkins Hospital Coronary Care Unit during a 1-month period with unstable angina or acute myocardial infarction (AMI) with the subsequent development of angina at rest. All were under the care of 1 cardiologist (J.T.F.) and all, therefore, were treated with a single therapeutic strategy. Two patients (nos. 16 and 17) still had chest pain after the addition of i.v. nitroglycerin and therefore underwent urgent coronary bypass surgery (Table I). Ten of the remaining 15 patients, having responded to the addition of i.v. nitroglycerin, had their infusion tapered and crossover to transdermal therapy accomplished *without* alteration of their concurrent medications and without addition of other antianginal or vasoactive (e.g., antihypertensive) medications. In these 10 patients an ischemic etiology for chest pain was documented by coronary angiography (9 patients) or by a documented MI (1 patient) (Table I). The remaining 5 patients

either required addition of other vasoactive drugs or did not have an ischemic cause for their chest pain documented. Two patients (nos. 11 and 12) with a prior history of hypertension required the addition of oral hydralazine or alpha methyldopa during crossover in order to control blood pressure. One patient (no. 13) had coronary spasm with near-normal coronary arteries demonstrated on coronary angiography and therefore had his dose of calcium blocker (nifedipine) increased empirically. The final 2 patients (nos. 14 and 15) had normal coronary arteries demonstrated on coronary angiography with negative results on ergonovine stimulation tests.

The transdermal nitroglycerin delivery systems maintained control of chest pain at rest in all 15 patients initially responding to the addition of i.v. nitroglycerin to their prior medical therapy. However, this study concentrates attention on the 10 patients with a documented ischemic cause for their chest pain and no change in antianginal or other vasoactive drugs during crossover (patients 1 to 10, Table I). In this well-defined subgroup, there were 8 men and 2 women (7 white and 3 black) and the mean age was 63 ± 10 years (± standard deviation). Six patients had an admission diagnosis of unstable angina. Four patients had AMI documented by an increase in MB–creatine kinase blood levels, and subsequently had unstable angina without reelevation of cardiac enzymes. Seven of the 10 patients had a history of MI. The mean duration of stable exertional angina before the present admission was 41 ± 42 hours. Four patients had undergone coronary artery bypass surgery and 1 patient had undergone transluminal angioplasty. All 6 patients with unstable angina without recent AMI had had multiple episodes of chest pain at rest during the 24 hours before admission to the coronary care unit. The 4 patients with post MI unstable angina had at least 1 episode of chest pain at rest during the 3 hours before the initiation of i.v. nitroglycerin therapy. All had obtained relief of their last chest pain episode with 1 or more sublingual nitroglycerin tablets (mean dose 1.1 ± 0.6 mg). Eight of the 10 patients were receiving calcium channel blockers and 3 patients were receiving β blockers before admission (Table II). In all patients, calcium channel blocker and β-blocker therapy was continued at the same doses given when they entered the coronary care unit during i.v. nitroglycerin therapy, during the subsequent crossover period and for at least 24 hours thereafter.

Experimental protocol: *Prospective study:* Baseline mean arterial pressure was determined by averaging 6 measurements of blood pressure taken at 5-minute intervals over a 30-minute period. Blood pressure was measured using an ultrasonic blood pressure cuff (Infrasonde), which displays systolic, diastolic and mean arterial pressure. The nitroglycerin solution was prepared by adding a 10-ml ampule of Tridil® (American Critical Care) that contained 50 mg of nitroglycerin to 500 ml of 5% dextrose in water or 0.9% normal saline solution in glass bottles to produce a final concentration of 100 μg/ml. If the infusion rate exceeded 160 μg/min, then the concentration of nitroglycerin was increased to 400 μg/ml by adding 4 ampules to 500 ml. A special polyethylene plastic administration set (Tridil Set, American Critical Care), into which absorption of nitroglycerin is less than 1%, was used with all infusions. The i.v. infusion of nitroglycerin was administered with an IMED 922 infusion pump at an initial rate of 4 to 5 μg/min and the infusion rate increased at prescribed intervals until a 10% reduction in mean arterial pressure was reached or systolic pressure decreased to 90 mm Hg. Blood pressure was measured 3 minutes after each change in infusion rate. If mean arterial pressure decreased 3% or less from baseline, the infusion rate was immediately increased to the next level. Dose increments were set at 5 μg/min between 5 and 20 μg/min, 10 μg/min between 20 and 40 μg/min, 20

μg/min between 40 and 80 μg/min, 30 μg/min between 80 and 200 μg/min and then 40 μg/min between 200 and 640 μg/min. If the mean arterial pressure decreased 4 to 6% from baseline after 3 minutes, then no change in infusion rate was made for a total of 10 minutes. If after 3 minutes the initial decrease in mean arterial pressure was 7% or more, then the infusion rate was returned to the previous rate for 10 minutes and a one-half increment attempted. When mean arterial pressure approached the desired level, fine adjustments to achieve the exact hemodynamic endpoint were carried out with increments of less than 50% of the previous increment, at 10-minute or more intervals. Back titration was allowed if the reduction in mean arterial pressure exceeded 10% or if adverse reactions occurred. Episodes of chest pain with associated electrocardiographic changes occurring during the titration period were treated with sublingual nitroglycerin before continuing titration. Crossover to transdermal nitroglycerin before discharge from the coronary care unit was carried out without a specific crossover protocol by the patient's attending cardiologist.

Retrospective study: The infusion of nitroglycerin was initiated at 4 to 5 μg/min, and the infusion rate was increased stepwise until a 10 to 15% reduction in mean arterial pressure was achieved. The final i.v. infusion rate, once achieved, was maintained for 8 to 48 hours. If the patient remained pain free, crossover to transdermal nitroglycerin patches was begun. Crossover was initiated by reducing the infusion rate of i.v. nitroglycerin by approximately 50% and a 5-mg/24-hour transdermal nitroglycerin patch was applied (Nitrodur®, Key Pharmaceuticals). If after at least 30 minutes of observation the systolic blood pressure had not increased at least 10%, the i.v. infusion rate was decreased further. If the systolic blood pressure increased at least 10%, or an episode of chest pain occurred, then another 5- or 10-mg/24-hour nitroglycerin patch was added. This sequence was repeated until the i.v. infusion was discontinued with the patient's blood pressure remaining at or near the level achieved with i.v. nitroglycerin. In 3 patients (nos. 4, 5 and 6) with initially low arterial pressures (mean arterial pressure between 72 and 88 mm Hg) after an initial 3 to 10% reduction had been obtained by cautious titration, mean arterial pressure was observed to increase above control levels before crossover to transdermal therapy. In these 3 patients, transdermal patches were titrated to reduce mean arterial pressure approximately 10% below this new baseline level. Additional 5- or 10-mg/24-hour patches could be applied if an episode of chest pain occurred after the initial blood pressure endpoint had been reached.

Results

Prospective study: The mean final infusion rate of i.v. nitroglycerin required to obtain a 10% reduction in mean arterial pressure was 64 ± 80 μg/min (range 5 to 250). Although the formal experimental protocol was complete 1 hour after reaching the final maintenance infusion rate, clinical outcomes were recorded up to the time of the patient's discharge from the coronary care unit. After reaching the final infusion rate, no further episodes of chest pain at rest occurred in 8 of the 9 patients studied (Table I). The remaining patient had a single episode of chest pain after 24 hours of i.v. therapy, but had no additional chest pain episodes after a single additional upward titration. Two of these 9 patients (nos. 4 and 8) subsequently underwent bypass surgery, not because of a recurrence of unstable angina, but because of the severity of the fixed coronary disease documented at coronary angiography. One of these 2 patients (no. 4) was maintained with i.v. nitroglycerin until surgery. One patient (no. 1), after undergoing cardiac catheterization, was believed not to be a surgical candidate because of the presence of extremely severe distal vessel disease and poor left ventricular function. The patient remained pain free for 10 days with i.v. nitroglycerin therapy before dying from left ventricular failure. Seven patients, including 1 of the patients who underwent elective surgery, were weaned off i.v. nitroglycerin and switched to transdermal nitroglycerin patches (5 to 20 mg/24 hours) without a specific crossover protocol. No further chest pain episodes occurred after crossover in any of these 7 patients up to the time of their discharge from the coronary care unit.

Hemodynamic changes: Systolic pressure was reduced after the addition of i.v. nitroglycerin from 130 ± 15 to 116 ± 15 mm Hg, a 10.9 ± 6.2% reduction from control. Mean arterial pressure was similarly reduced from 95 ± 10 to 85 ± 9 mm Hg, a 10.6 ± 1.8% reduction from baseline (range 7 to 13%).

Clinical outcome: Three patients had transient episodes of chest pain during upward titration of the nitroglycerin infusion. Six patients had no alteration of their antianginal regimen with the exception of nitrates (Table II). In 1 patient nifedipine was increased from 40 to 80 mg/day and in another patient nifedipine was added at 120 mg/day for empirical reasons, despite no further episodes of chest pain after reaching the final infusion rate of i.v. nitroglycerin. In the remaining patient propranolol was increased from 60 to 80 mg/day, again despite no further chest pain having occurred.

Retrospective study: In the subgroup of 10 patients included in our retrospective study, the mean duration of i.v. nitroglycerin treatment was 36 ± 26 hours, and the mean final infusion rate was 84 ± 74 μg/min (range 10 to 200). One patient had a single episode of chest pain after the initial hemodynamic endpoint had been reached, prompting an additional upward step of titration to the final maintenance infusion rate. After the final maintenance infusion rate had been established, none of the 10 study patients had further episodes of chest pain. During the crossover period the i.v. infusion rate was decreased stepwise at 51 ± 31-minute intervals until the infusion was discontinued. Crossover was accomplished by stepwise addition of nitroglycerin patches at 104 ± 74-minute intervals using 5- or 10-mg/24-hour dose increments (mean 7.5 mg/24 hours), attempting to maintain as closely as possible the mean arterial pressure level achieved after initiation of i.v. therapy. Two patients (nos. 5 and 10) had an episode of chest pain during the first 24 hours after the initial blood pressure–defined crossover had been carried out. In both patients, an additional 10-mg/24-hour dose of transdermal nitroglycerin was required to restore blood pressure, which had increased during the interim from its initial level after crossover. Both patients remained pain free after this final transdermal dose was established (22.5 ± 10 mg/24 hours [range 5 to 40]). The mean interval required for crossover was 4.8 ± 2.8 hours.

Hemodynamic changes: Mean control systolic blood pressure was 138 ± 20 mm Hg. After institution of i.v. nitroglycerin therapy, systolic pressure was reduced to 117 ± 14 mm Hg, a mean decrease of 14 ± 8% from the

control level ($p < 0.001$) (Fig. 1). One hour after crossover to the transdermal nitrate preparation, systolic pressure was 114 ± 1 mm Hg, which was not significantly different from 112 ± 19 mm Hg measured just before the tapering of i.v. therapy was begun. Likewise, 24 hours after crossover, systolic pressure was 115 ± 15 (not significant [NS] vs levels after final i.v. or 1 hour after crossover). The mean control diastolic pressure was 82 ± 19 mm Hg, decreasing from 12 ± 5% to 73 ± 11 mm Hg after initiation of i.v. nitroglycerin ($p < 0.001$). One hour after crossover to transdermal therapy, diastolic pressure was 70 ± 8 mm Hg (NS vs 73 ± 10 mm Hg measured before tapering the i.v. infusion). The average control mean arterial pressure was 101 ± 18 mm Hg, decreasing from 12 ± 8% to 87 ± 11 mm Hg after titration of the i.v. infusion ($p < 0.001$) (Fig. 1). One hour after crossover to nitroglycerin by transdermal delivery, the mean arterial pressure was 85 ± 9 mm Hg (NS vs 86 ± 11 mm Hg measured just before crossover was begun). Likewise, 24 hours after crossover, mean arterial pressure was 85 ± 11 mm Hg (NS vs levels after final i.v. or 1 hour after crossover). The mean heart rate was 75 ± 18 beats/min during the control period, 75 ± 13 beats/min before tapering of i.v. nitroglycerin was begun, and 76 ± 11 beats/min 1 hour after crossover to transdermal therapy (NS).

Clinical outcome: During the 24-hour period after crossover to the final transdermal nitroglycerin dose, no further episodes of chest pain occurred in the 10 patients under discussion. Seven of the 10 patients had no further episodes of chest pain at rest during the remainder of their hospitalization and were discharged with the same medical regimen given at the time of their transfer from the coronary care unit. One patient (no. 1) had recurrent chest pain episodes at rest 8 days after discharge from the coronary care unit. This patient failed to respond to the reinstitution of i.v. nitroglycerin and immediately underwent coronary bypass surgery. The 2 remaining patients each had a recurrent episode of chest pain at rest after transdermal nitroglycerin therapy was discontinued (patient 4) or the dose was reduced (patient 8) 4 days after discharge from the coronary care unit. After transdermal nitroglycerin had been restarted (patient 4) or the dose restored (patient 8), neither patient had further episodes of chest pain and were discharged from the hospital receiving the same dose of transdermal nitroglycerin given at the time of their discharge from the coronary care unit. The only change in medical regimen before hospital discharge occurred in patient 4 who had taken atenolol, 50 mg once a day (added empirically to his medical regimen on day 2), despite apparent clinical success with transdermal nitroglycerin alone.

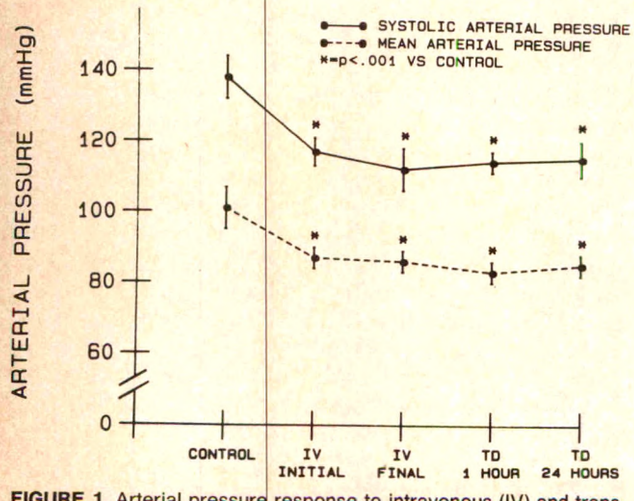

FIGURE 1. Arterial pressure response to intravenous (IV) and transdermal (TD) nitroglycerin. **Solid line** indicates systolic pressure during control period before initiation of IV nitroglycerin. IV final = systolic pressure at the end of the IV infusion just before beginning tapering; IV initial = systolic pressure after initial titration; TD 1 hour = systolic pressure 1 hour after crossover to the TD preparation; TD 24 hours = systolic pressure 24 hours after crossover.

Adverse reactions: In 2 patients, minor adverse reactions were noted during upward titration of the i.v. nitroglycerin infusion. Both had transient hypotension, which was corrected immediately by decreasing the infusion rate; 1 had associated transient sinus bradycardia (54 beats/min).

Methods of data analysis: All data are presented as mean ± standard deviation. Statistical analysis used 2-tailed Student *t* tests for paired values.

Discussion

Intravenous nitroglycerin has been demonstrated to be effective therapy for congestive heart failure complicating AMI,[7] for acute hypertension developing during and after cardiac surgery,[8,9] and for the induction of controlled hypotension during certain surgical procedures.[10,11] Intravenous nitroglycerin is also a valuable addition to our medical management of unstable angina when episodes of chest pain continue to occur at rest despite maximal nonparenteral medical therapy.[3–5] In the present study, all 9 patients entered into the prospective titration protocol and 15 of 17 consecutive patients examined retrospectively became pain free after addition of i.v. nitroglycerin to their prior medical therapy.

The choice of a 10% reduction in mean arterial pressure as the initial titration endpoint was arbitrary, but was the same endpoint that was found to be safe and effective in our recent randomized, placebo-controlled clinical trial of i.v. nitroglycerin treatment in patients with AMI.[12] During previous studies using short-term infusion of i.v. nitroglycerin, invasive hemodynamic monitoring documented that by the time that a 10% reduction in mean arterial pressure had been reached, significant reductions in both left ventricular filling pressure and peripheral vascular resistance had already been achieved.[7,13] Although a 10% reduction in mean arterial pressure was used as the titration endpoint in the present study, it may be more convenient for most coronary care units (in which mean arterial pressure determination must be done manually) to titrate to a 10 to 20% reduction in systolic arterial pressure, depending on the patient's baseline blood pressure.

Three previous studies document the efficacy of i.v. nitroglycerin in unstable angina unresponsive to standard medical therapy. Kaplan et al[4] reported that 25 of 35 patients (71%) became pain free and 8 others (23%) achieved a more than 50% decrease in the number of episodes per day of angina at rest. Success rates of 74 to

86% were reported by Mikolich et al[3] in 47 patients. Curfman et al[5] also observed a significant decrease in the number of pain episodes per day. However, only 5 of 14 patients (36%) became pain free. Curfman's protocol required administration of a dose of β blocker sufficient to reduce heart rate at rest to less than 55 beats/min before the initiation of i.v. nitroglycerin therapy. Beta blockers potentiate coronary vasoconstriction in patients with vasospastic angina, presumably by allowing unopposed α-adrenergic stimulation.[14,15] In the presence of 50% or greater luminal narrowing by a fixed eccentric coronary lesion, even a small change in the remaining circumference of the vessel would result in a marked decrease in blood flow to the region of myocardium supplied by that vessel (i.e., "a dynamic stenosis").[16,17] This discussion is not meant to imply that β blockers may not be beneficial in some subgroups of patients with unstable angina. In a recently completed double-blind randomized placebo controlled trial, Gottlieb et al,[18] at this institution, demonstrated a decrease in the frequency of symptomatic and asymptomatic ischemic episodes with propanolol therapy in patients with unstable angina who were already receiving nitrates and the calcium blocker, nifedipine.

Chierchia et al[19] documented in the catheterization laboratory that the initial abnormality during an episode of angina at rest was a decrease in coronary sinus O_2 saturation, suggesting a decrease in O_2 supply rather than an increase in O_2 demand. Based on these considerations, management of unstable angina should concentrate on pharmacologic therapies that act primarily, although not solely, on the supply side of the myocardial supply/demand equation. Nitrates not only decrease systolic arterial pressure and left ventricular end-diastolic pressure (primary determinants of myocardial oxygen demand), but also dilate large extramural coronary arteries and some eccentric coronary stenoses, thereby potentially increasing myocardial O_2 supply. Nitroglycerin may also improve myocardial O_2 supply by dilating intercoronary collateral channels. By dilating collateral vessels, nitroglycerin could increase blood flow to ischemic regions of myocardium supplied by severely stenosed or even occluded vessels.[20,21] Calcium channel blockers reduce arterial pressure, peripheral vascular resistance and myocardial contractility, which act to reduce myocardial O_2 demand. Like nitrates, calcium channel blockers also act to improve O_2 supply by dilating or preventing vasospasm in large extramural coronary arteries. Beta blockers, in contrast, act primarily on the demand side by decreasing heart rate and contractility, and only secondarily on the supply side by redistributing coronary blood flow to deeper subendocardial layers.[22]

Transcutaneous delivery of nitroglycerin can be accomplished by application of 2% nitroglycerin ointment every 4 to 6 hours for prophylactic treatment of angina. However, nitroglycerin ointment is inconvenient to apply and the surface area of application becomes an important uncontrolled variable. Reichek et al[23] reported that nitroglycerin ointment in doses of 1.5 to 19.0 mg significantly decreases systolic arterial pressure and significantly increases heart rate and exercise duration in patients with stable exertional angina 1 and 3 hours after application. After 2 to 3 months of administration, significant hemodynamic and antiischemic effects could still be demonstrated. Their study design involved progressive dose titration in individual patients.

The new transdermal delivery systems, in addition to being more convenient, precisely control the surface area of skin used for drug delivery. Muller et al[6] reported uniform plasma concentrations of nitroglycerin for 24 hours after application of 1 or more transdermal patches. Hemodynamic effects appeared to be relatively constant between 2 and 10 hours after patch application, with some attenuation or decrease in the magnitude of the hemodynamic effects evident at the end of 24 hours. However, peripheral venous plasma concentrations were low (0.03 to 0.72 ng/ml) when doses of 5 to 20 mg/24 hours were used, compared with 0.1 to 2.24 ng/ml after use of 0.6-mg doses of sublingual nitroglycerin or 12-mg doses of 2% nitroglycerin ointment.[24]

Acute clinical studies testing transdermal nitroglycerin delivery systems in patients with stable angina pectoris generally have revealed improved exercise tolerance 2 to 6 hours after patch application but have yielded conflicting results after 24 hours. Thompson,[25,26] in a double-blind, placebo-controlled, crossover study, using doses of 10 to 20 mg/24 hours, reported significant increases in the duration of exercise after 2 and 26 hours. Hollenberg and Go[27] documented an increase in exercise time to 1 mm of ST-segment depression with 2.5 to 10-mg/24-hour doses of transdermal nitroglycerin, which was comparable to the increase obtained with sublingual nitroglycerin. In contrast, Reichek et al,[28] in a double-blind, placebo controlled trial, reported increased exercise duration 4 and 8 hours after patch application, but minimal effects after 24 hours using "maximally tolerated" transdermal nitroglycerin doses of 20 to 25 mg/24 hours. At smaller doses (mean 9 mg/24 hours) Reichek et al found no significant increase in exercise duration at any time point. However, the presence of other antianginal drugs in most of their patients may have limited the magnitude of benefit obtainable from nitroglycerin alone. Parker and Fung,[29] using doses of 15 to 45 mg/24 hours, showed dose-dependent reductions in systolic blood pressure and increases in exercise duration at 2 and 4 hours, but at 24 hours differences were significant only for the 45-mg/24-hour dose. The need for higher doses was also emphasized by Rajfer et al[30] in a study performed in patients with congestive heart failure. Transdermal nitroglycerin at a mean dose of 26 $\pm$ 3 mg/24 hours reduced left ventricular filling pressure and systemic vascular resistance and increased stroke volume and cardiac index throughout the 24-hour period after patch application.

The present study shows that a wide range of nitroglycerin infusion rates (10 to 200 μg/min) were required to reach the same hemodynamic endpoint in individual patients. Likewise, a wide range of transdermal patch doses (5 to 40 mg/24 hours) were required to accomplish crossover. These findings emphasize the need for individual patient titration and suggest the need for higher dose patches (20 to 40 mg/24 hours) if high-dose transdermal therapy is to be continued chronically.

The present study has at least 2 design limitations. First, the formal crossover study was retrospective. Second, no placebo-treated control group was studied. Although all or part of the clinical improvement could have occurred spontaneously, several admittedly anecdotal observations tend to support a beneficial role of nitroglycerin. The 2 patients in whom transdermal nitrate therapy was either reduced or discontinued immediately had an episode of chest pain at rest. Furthermore, both these patients became pain free when transdermal nitroglycerin treatment was restored to its previous dose. In addition, the 2 patients who had an episode of chest pain during the first 24 hours after crossover had no further chest pain after their transdermal dose was increased by 10 mg/24 hours. Finally, this short-term study does not consider the issue of hemodynamic attenuation. Whether higher transdermal doses and/or a nitrate-free period will be necessary to optimize antianginal effects during long-term therapy awaits the results of ongoing clinical trials.

In summary, the results of the present study, while not ruling out the possibility of spontaneous improvement, do suggest that the addition of i.v. nitroglycerin to prior oral antianginal therapy, followed by crossover to transdermal nitroglycerin, is a safe and effective means of managing patients with unstable angina.

Ischemia During Angioplasty After Streptokinase: A Marker of Myocardial Salvage

LOWELL F. SATLER, MD, CHARLES E. RACKLEY, MD, CURTIS E. GREEN, MD, RANDOLPH S. PALLAS, MD, DAVID L. PEARLE, MD, ALBERT A. DEL NEGRO, MD, and KENNETH M. KENT, MD, PhD

Although thrombolytic therapy can result in lysis of a coronary artery thrombus, salvage of myocardium as measured by enzymatic, electrocardiographic and regional wall motion evaluation has not been clearly documented. Many patients after successful reperfusion continue to experience recurrent chest pain. The presence of recurrent chest pain suggests salvaged myocardium. Controlled reocclusion of the infarct vessel with the use of coronary angioplasty may support evidence for myocardial salvage. Experience in 50 patients who underwent angioplasty was reviewed retrospectively. Sixteen of the 50 patients had electrocardiographic or clinical evidence of ischemia at the time of balloon inflation. Prospectively, all patients who underwent angioplasty after they had received streptokinase were evaluated, and 5 of 5 patients had chest pain and ST-segment elevation during balloon inflation. The development of ischemic changes during balloon catheter inflation suggests the presence of persistently viable, salvaged myocardium after successful thrombolysis. (Am J Cardiol 1985;56:749–752)

Potential myocardial salvage as a result of thrombolytic therapy during acute myocardial infarction (AMI) has not been proved. Improvements in regional and global function have been inconsistent.[1–4] Nevertheless, many patients have recurrent chest pain after successful thrombolysis.[5] Ischemic pain is presumably a result of transient reocclusion of the infarct-related vessel, suggesting residual viable myocardium. Rather than evaluating the effects of spontaneous transient reocclusion, a more precise method for detecting viable myocardium would be controlled reocclusion of the infarct-related vessel accomplished during coronary angioplasty. The development of electrocardiographic (ECG) changes or chest pain during angioplasty balloon inflation was retrospectively analyzed in patients recently treated with intracoronary or intravenous streptokinase (SK) for an AMI. Then, ischemic manifestations during angioplasty were prospectively evaluated in all subsequent patients receiving intravenous SK for AMI.

Methods

During an 18-month period, 130 patients with AMI received SK: 87 received intracoronary SK, 36 received intravenous SK and 7 received intravenous followed by intracoronary SK. Criteria for the infusion of SK included: age younger than 70 years; chest pain less than 12 hours in duration; and more than 1.0 mm of ST elevation, suggestive of transmural injury. In patients receiving intravenous SK who had persistent chest pain 90 minutes after infusion, emergency angiography was performed to assess vessel patency and intracoronary SK was infused if the infarct vessel was occluded. Myocardial necrosis was confirmed by elevation of creatine kinase isoenzyme levels in all patients. Fifty patients had coronary angioplasty performed 30 minutes to 72 hours after SK administration for: recurrent chest pain and ECG changes in the distribution of the infarct vessel; and/or greater than 70% residual stenosis of the infarct vessel. During intravenous nitroglycerin infusion, at least 3 inflation-deflation dilatation sequences were completed, ranging from 30 to 90 seconds. The minimal peak inflation pressure was 2 atmospheres higher than the balloon indentation resolution pressure. Side branch occlusion was not noted during or after angioplasty. New evidence for myocardial ischemia during angioplasty was considered to be chest pain during balloon inflation similar to previous pain of infarction or ECG changes during balloon inflation, consisting of ST elevation or depression. (The electrocardiogram was typically a single channel, recording only lead 2 or lead 3.)

Prospectively, all subsequent patients who received intravenous SK were evaluated by determining if the same markers for ischemia were present during angioplasty. Five of the next 7 sequential patients who received intravenous SK with clinical evidence for reperfusion had patent infarct-related vessels and underwent successful angioplasty.

Left ventricular wall motion abnormalities were evaluated by subjective assessment of the single-plane (45° right anterior oblique) or biplane contrast (45° right anterior oblique/25° cranial–60° left anterior oblique) ventriculograms, except in 2 patients who had nuclear ventriculograms because of clinical instability.

Results

Sixteen of the 50 patients who underwent angioplasty had chest pain or ischemic ECG changes during balloon

Abbreviations as in Table I.

inflation (Table I). The infarct-related vessel was the left anterior descending artery in 6 patients (38%), the right coronary artery in 9 patients (56%) and the left circumflex in 1 patient (6%). Collaterals to the infarct-related vessel were noted in 4 (25%). The average duration of chest pain before intervention was 300 ± 330 minutes. The average global ejection fraction for the group was 56 ± 13%. Wall motion abnormalities were identified in 88% of the patients: 40% had akinesia or dyskinesia in the infarct-related zones, 24% had both akinesia and hypokinesia in the infarct-related zones, 24% had hypokinesia alone in the infarct-related segments, and 12% had no wall motion abnormalities.

During balloon inflation, 1 patient had chest pain only, 6 patients had ECG changes only and 6 had both chest pain and ECG changes. In 1 patient, balloon inflation resulted in occlusion of the infarct vessel with the development of ST changes but no pain. Two other patients had marked chest pain before angioplasty, but after balloon inflation, which resulted in an improvement in anterograde flow, chest pain rapidly resolved (Table I). Typical ECG changes during balloon inflation are shown in Figure 1.

Five sequential patients underwent coronary angioplasty 48 hours after intravenous SK administration (Table II). All showed wall motion abnormalities in the distribution of the infarct-related artery. All patients had chest pain and ST-segment elevation during balloon inflation. Thus, balloon occlusion of the infarct-related vessel produced or relieved myocardial ischemia in 21 of 55 post-AMI patients.

Discussion

The goal of aggressive treatment in AMI is to decrease infarct size by limiting necrosis. Thrombolytic treatment for AMI has not clearly resulted in a reduction in

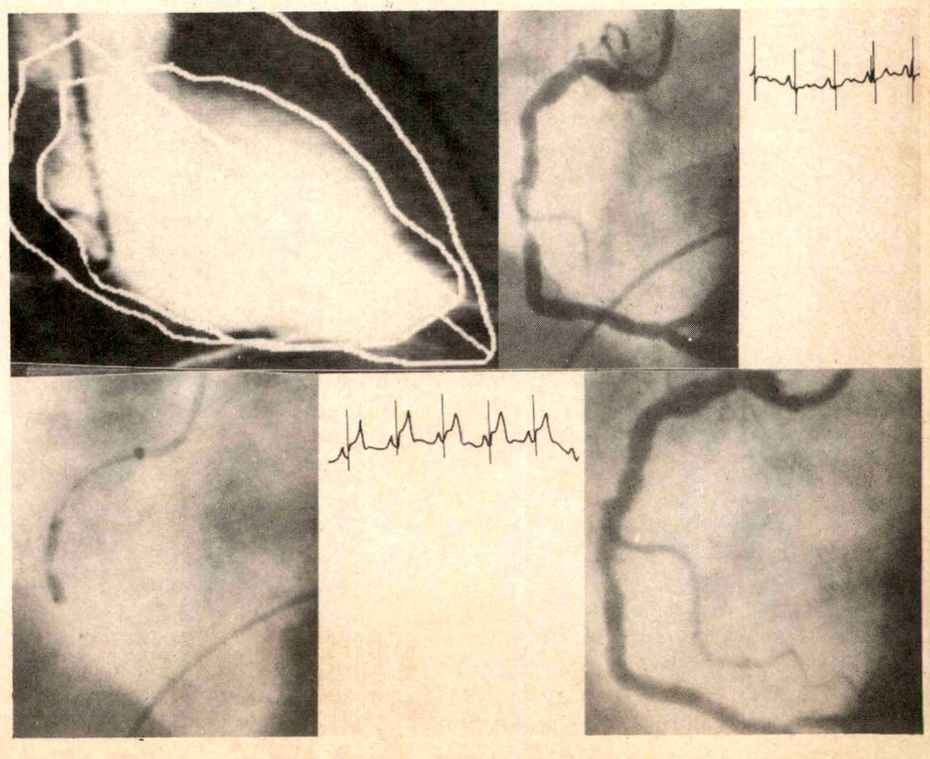

FIGURE 1. Top left, ventriculogram of study patient 48 hours after intravenous streptokinase administration showing akinesia in the diaphragmatic segment and hypokinesia in posterobasal segment. Top right, angiogram of the right coronary artery with a 70% midstenosis 48 hours after infusion of intravenous streptokinase. The simultaneous electrocardiogram is shown. **Bottom left,** coronary angioplasty balloon inflated in the right coronary artery. Patient had marked ST elevation and chest pain. **Bottom right,** final angiographic result after angioplasty.

the area of necrosis.[1–4] Inherent problems with the techniques for assessing infarct size, however, make determination of reduction difficult. Creatine kinase–MB isoenzymes cannot be used to estimate the extent of myocardial necrosis,[6–8] because reperfusion results in "washout" of enzymes from necrotic areas so that the relation between infarct size and enzyme levels is not proportional. Electrocardiographic mapping is limited in that it can be applied only in anterior or lateral infarcts,[9,10] and the absolute height of the ST segment is affected by intraventricular conduction defects, artificial pacemakers, pericarditis, chest wall thickness and intervening lung tissue.[11] Finally, measurements of regional wall motion to assess infarct size are limited by the inability to differentiate infarction from ischemia. In addition, there is often a lagging return of mechanical function even when reperfusion involves reversibly injured myocardium, a condition referred to as "stunning" of the myocardium.[12,13]

Clinical myocardial ischemia is characterized by the development of chest pain and confirmed by ECG, hemodynamic and wall motion abnormalities, which return to normal after the ischemic episode. If reperfusion of infarcted myocardium salvages tissue, then subsequent transient interruption of coronary flow at the same anatomic site should produce ischemia manifested by chest pain or ECG changes. This is supported by recurrent episodes of clinical ischemia observed in patients after SK administration.

The present study was undertaken to examine the effects of transient balloon occlusion of coronary blood flow at the stenotic site after thrombolysis to detect the presence of viable myocardium in the previous area of myocardial infarction. Myocardial ischemia was documented in 14 patients undergoing angioplasty during balloon inflation. Transient reocclusion resulting in myocardial ischemia can only indicate the presence of preserved viable myocardium. In 2 other patients, ischemia was resolved with improvement in anterograde flow as a result of successful angioplasty.

The actual percentage of patients with ischemia at the time of angioplasty may be higher than the initial 32% (16 of 50) documented by retrospective review because (1) ECG changes and chest pain at the time of angioplasty were not systematically recorded; (2) monitoring of the electrocardiogram was predominantly in leads 2 or 3, which would have resulted in underestimation of ischemic changes in balloon inflation in the left anterior descending artery; (3) all patients were receiving nitroglycerin at the time of infusion, which decreases the potential for provoking ischemia; (4) the duration of balloon inflation was variable, and more prolonged inflation could have precipitated ischemia; and (5) collateral flow can attenuate ischemia and again decrease the potential for provoking ischemia. Prospective evaluation of 5 patients who had successful coronary angioplasty, however, revealed both chest pain and ST changes compatible with ischemia at the time of balloon inflation.

The major limitation of the investigation concerns the patients in whom a subtotal occlusion was identified before the administration of SK, and the group of patients who received intravenous SK, where infarct vessel patency was not initially angiographically identified. Although one may conclude that SK can result in no benefit to patients with subtotally occluded vessels, continued transient or even complete reocclusion of the vessel may occur,[14] and establishment of a lytic state may be important in maintaining vessel patency to preserve left ventricular function. In the patients receiving intravenous SK in which initial infarct vessel patency was not angiographically identified, we have used the standard clinical criterion for identifying successful lysis: resolution of chest pain shortly after infusion of the agent.[15–17] In patients with persistent chest pain, emergency catheterization was performed to evaluate the infarct vessel, at which time intracoronary SK was administered if there was occlusion. Hence, we believed that SK therapy was important in either initiating or maintaining infarct vessel patency in all patients.

Although the methods of assessing salvage after reperfusion have limitations, the presence of recurrent ischemic events after successful thrombolysis suggests viable myocardium. Although major left ventricular wall motion abnormalities persist, recurrent ischemia during angioplasty after SK administration in a significant number of patients supports the concept of preserved viable myocardium.

Saudi Arabia

Graduate Cardiologist and Senior Cardiologist in Adult Cardiology

The Riyadh Cardiac Center, based in the Armed Forces Hospital, Riyadh, provides a full range of cardiac services to patients drawn from the Arabian Peninsula. Busy unit is principal referral center for the Kingdom of Saudi Arabia and, therefore, handles a high proportion of seriously ill patients. There is a wide spectrum of disease particularly Rheumatic and Congenital Heart Disease sequelae in adults, in addition to Coronary Artery Disease.

There are four divisions: Adult Cardiology, Pediatric Cardiology, Cardiac Surgery (including neonates), and Cardiac Anesthesia.

The Adult Cardiology Division presently has 4 Consultants, with a minimum of 5 years experience at senior level required – 2 Senior Registrars, equivalent to Senior Cardiologist, with a minimum of 2 years experience in Cardiology – 2 Registrars, Graduate Cardiologist – all with American Board of Internal Medicine Certification or equivalent.

Approximately 650 cardiac surgery procedures are performed annually. The Riyadh Cardiac Center provides higher professional training of Saudi Nationals, with daily teaching program; teaching background is desirable.

Interested applicants send resume, copies of diplomas and certificates, 2 passport-type photos, and salary history to:

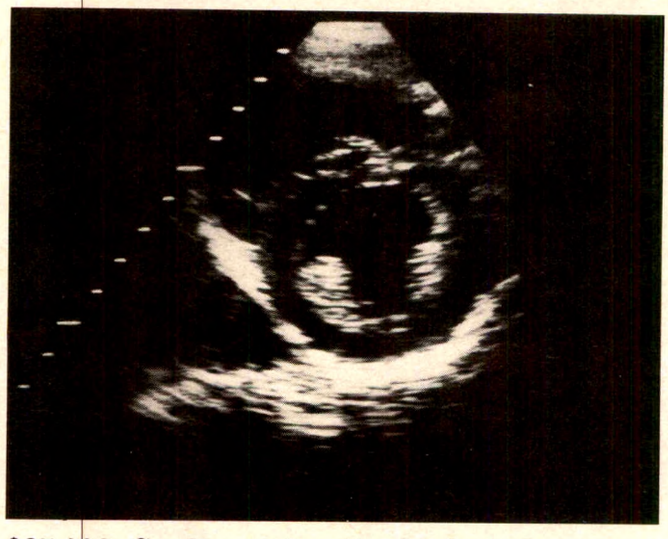
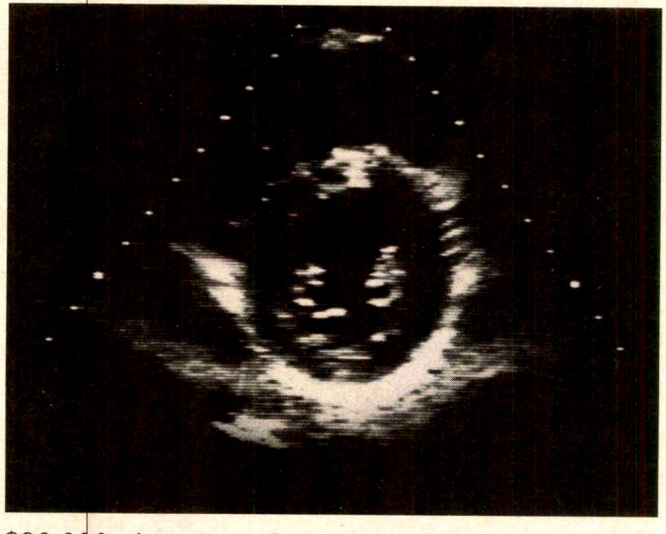
The only difference in Cardioscan's image is the cost.



$25,000 Cardioscan's affordable image looks like this.



$90,000 At more than three times the cost of Cardioscan, their image looks the same.

Until now, sophisticated, high-resolution echocardiography came with a high price tag. To get images like the one at the top you had to pay the cost at the bottom. Interspec has changed all that. We developed Cardioscan™—the easy-to-use echocardiography system that makes high-quality ultrasound imaging not only possible, but *affordable.*

Unlike other low-cost systems, Cardioscan doesn't sacrifice performance for price. You get all the advantages of larger, hospital-scale units—plus, some features often not available even on more expensive systems.

And, Cardioscan has been designed with the future in mind. You do not have to be concerned about your system becoming obsolete as echocardiographic technology advances or your clinical needs change. Your system will be fully upgradeable to keep pace with the demands of your practice.

The best technology packaged in a lightweight, compact design

There is only one way to understand the quality Cardioscan delivers. And that is to compare it with other units. Even when judged against systems costing three times as much, Cardioscan more than measures up.

More reasons to decide on Cardioscan

- Superior image quality and resolution in both 2-D and M-mode.
- Logically grouped, easy-to-learn controls let you concentrate on the patient, not the instrument.
- On-line or off-line calculations capability means calculations and annotations can be performed during patient examinations, or later *in video playback.*
- Triple image memory means you can store up to three images and select the preferred one for calculations and/or hard copy.

- ECG with dual trigger enables automatic viewing of end-systolic and end-diastolic images from the same cardiac cycle.
- Small, lightweight transducer available in a variety of frequencies and focal zones helps make Cardioscan adaptable to a wide range of applications.

The Cardioscan Doppler

In keeping with Interspec's commitment to cardiology, Cardioscan has been designed to accept major upgrades. One of the first of these is the Cardioscan Doppler, which adds noninvasive hemodynamics to your diagnostic capabilities. With pulsed, high PRF, continuous wave and comprehensive calculations, this Doppler is truly state-of-the-art.

Reliable service

Because Cardioscan is made in the U.S., availability of parts is never a problem. A complete service policy includes rapid response to calls and a loaner program to assure maximum up-time.

Compare our image. Compare our price.
Compare our features.

Initial therapy should
patients off right

start hypertensive.

Minipress® for initial therapy
(prazosin HCl)

- Is effective when used alone
- Does not cause a significant incidence of sexual impotence, although it has been reported[1]
- Does not adversely affect blood lipids*[2]
- Does not lower heart rate, cardiac output or work capacity[3]
- Does not induce potassium wasting[4]
- The most common side effects with Minipress are: dizziness, headache, drowsiness, lack of energy, weakness, palpitations, nausea. With Minipress therapy there is a tendency for side effects to diminish with time. Syncope (sudden loss of consciousness) has been reported in about 0.15% of patients at an initial dose of 1 mg and in about 1% of patients at an initial dose of 2 mg

*Minipress is not indicated for the treatment of hyperlipidemia.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

for Initial Therapy in Hypertension

Please see Minipress brief summary on following page.

© 1983, Pfizer Inc.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

Brief Summary
MINIPRESS® (prazosin hydrochloride) Capsules ***For Oral Use***
INDICATIONS: MINIPRESS (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
WARNINGS: Minipress may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120–160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS. The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution. (See DOSAGE AND ADMINISTRATION.) Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.
If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.
Patients should always be started on the 1 mg capsule of MINIPRESS. The 2 and 5 mg capsules are not indicated for initial therapy.
More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS therapy.
Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS in pregnancy has not been established. MINIPRESS is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.
Usage in Children: No clinical experience is available with the use of MINIPRESS in children.
ADVERSE REACTIONS: The most common reactions associated with MINIPRESS therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.
The following reactions have been associated with MINIPRESS some of them rarely. (In some instances exact causal relationships have not been established.)
Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.
Cardiovascular: edema, dyspnea, syncope, tachycardia.
Central Nervous System: nervousness, vertigo, depression, paresthesia.
Dermatologic: rash, pruritus, alopecia, lichen planus.
Genitourinary: urinary frequency, incontinence, impotence, priapism.
EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.
Other: diaphoresis.
Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances the exact causal relationship has not been established because the baseline observations were frequently inadequate.
In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.
DOSAGE AND ADMINISTRATION: The dose of MINIPRESS should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:
Initial Dose: 1 mg two or three times a day. (See WARNINGS.)
Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.
Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.
OVERDOSAGE: Accidental ingestion of at least 50 mg of MINIPRESS in a two year old child resulted in profound drowsiness and depressed reflexes. No decrease in blood pressure was noted. Recovery was uneventful.
Should overdosage lead to hypotension, support of the cardiovascular system is of first importance. Restoration of blood pressure and normalization of heart rate may be accomplished by keeping the patient in the supine position. If this measure is inadequate, shock should first be treated with volume expanders. If necessary, vasopressors should then be used. Renal function should be monitored and supported as needed. Laboratory data indicate MINIPRESS is not dialysable because it is protein bound.
TOXICOLOGY: Testicular changes, necrosis and atrophy have occurred at 25 mg/kg/day (60 times the usual maximum recommended dose of 20 mg per day in humans) in long term (one year or more) studies in rats and dogs. No testicular changes were seen in rats or dogs at the 10 mg/kg/day level (24 times the usual maximum recommended dose of 20 mg per day in humans). In view of the testicular changes observed in animals, 105 patients on long term MINIPRESS (prazosin hydrochloride) therapy were monitored for 17-ketosteroid excretion and no changes indicating a drug effect were observed. In addition, 27 males on MINIPRESS (prazosin hydrochloride) alone for up to 51 months did not demonstrate changes in sperm morphology suggestive of drug effect.
HOW SUPPLIED: MINIPRESS is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

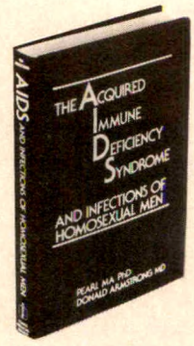
AIDS
An important new book on today's most virulent epidemic



From the Publishers of The American Journal of Medicine, The American Journal of Surgery, and Cutis

Acquire Immune Deficiency Syndrome (AIDS) and Infections of Homosexual Men

edited by **Pearl Ma, PhD,** and **Donald Armstrong, MD** with a foreword by **David J. Sencer, MD,** *Commissioner of Health, New York City; formerly Director, Centers for Disease Control, Public Health Service, U.S. Department of Health and Human Services*
0-914316-38-9, 442 pages, illus., 1984, $39.50

The first scientific presentation to review all the facts in full

AIDS has become one of the most publicized diseases in modern times. It has produced fear and confusion in the general public and presented a formidable challenge to the medical community. Physicians and scientists have begun work on managing this epidemic, disease control centers continue to search for answers, and the federal government has declared AIDS the number one health priority of the nation. Understanding this disease demands cooperation between many different medical specialties, and papers on this subject have been published in many diverse journals not regularly read by individual specialists. Now, for the first time, two highly distinguished medical experts, Drs. Pearl Ma and Donald Armstrong, have coordinated in one easily accessible volume the complete range of interdisciplinary approaches to this complex disease, with contributions by the most eminent researchers and physicians in disease control and hospital teaching centers throughout the country. Comprehensive coverage is given to the entire spectrum of sexually transmitted diseases, and an additional section on diagnostic perspectives offers never before published material on why this syndrome occurs primarily among homosexual men. For any physician or other health care professional interested in the prevention and cure of this modern epidemic, this book is an indispensable guide to recognizing and treating AIDS and other sexually transmitted diseases.

Table of Contents

• PART I SEXUALLY TRANSMITTED DISEASES — NONDIARRHEAL • PART 2 SEXUALLY TRANSMITTED DISEASES — DIARRHEAL • PART 3 OTHER SEXUALLY TRANSMITTED DISEASES • PART 4 INFECTIOUS AND NEOPLASTIC COMPLICATIONS OF AIDS • PART 5 IMMUNOLOGICAL EVALUATION METHODS AND CONTROLS • PART 6 DIAGNOSTIC PERSPECTIVE

CARDIOLOGIST (Non-Invasive) to associate with two board certified Cardiologists in twenty-two member multi-specialty clinic. Board certified or board eligible. Guaranteed salary with incentive bonus. Clinic is located in the heart of the Florida citrus industry and lake country. 1½ hours to either coast. Immediate drawing area—90,000. For additional information, send C.V. to: Box 465, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

PHARMACEUTICAL CAREER OPPORTUNITIES. We have assignments for entry and experienced physicians in the pharmaceutical industry. Send your curriculum vitae in confidence to: Bruce Rogers Co., Management Consultants, 20 Main St., Port Washington, NY 11050. (516) 883-1058.

CARDIOLOGIST—Progressive, university affiliated New England community hospital seeking state-of-the-art trained interventional cardiologist to develop angioplasty program, direct cardiac cath lab and be Assistant Chief of Cardiology. Outstanding opportunity to direct, teach, practice and do clinical research in rewarding environment. Reply with C.V. to Box 450, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

CARDIOLOGIST

Non-invasive/invasive Certified/Eligible Nuclear/Electrophysiology preferred (but not required) to join two man multifaceted practice in Sun Belt area. Practice is hospital base, consultative, office, CATH, including PTCA, pacemakers, non-invasive testing, including 2D Echo and Nuclear. Salary first year leading to partnership. Send CV to Box 445, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

Cardiologist Wanted—A large Cardiology Practice in a major Northeastern City is seeking a well qualified Cardiologist to join an established Referral Cardiology Practice. The Practice offers well rounded clinical, invasive and non-invasive opportunities, affiliation with a major Medical Center, and a large private Teaching Hospital. Please send letter and curriculum vitae to Reply Box 470, The American Journal of Cardiology, 875 Third Ave., New York, N.Y. 10022.

PEDIATRIC CARDIOLOGIST

Position available for an Assistant or Associate Professor at Hahnemann University. Inquiries and CV to Division of Pediatric Cardiology, Broad & Vine, Philadelphia, PA 19102 (215) 448-8852.

CARDIOLOGIST

To join consultative cardiology practice for large referral area. Training in cardiac catheterization, PTCA and non-invasive mandatory. Located in South. Send C.V. and details about your interests to Box 435, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

Cardiologist, non-invasive, to join six man Internal Medicine Group in the Piedmont area of N.C. Excellent practice opportunity, good starting salary, ownership opportunity in one year. Immediate opening available. Please send curriculum vitae to: Box 460, The American Journal of Cardiology, 875 Third Ave., New York, N.Y. 10022.

The finer art of pacemaking.

See Genisis™ and other fine Pacesetter and Siemens-Elema pacing products at island exhibit #4004, American Heart Association Meeting.

Introducing Genisis™

Dual chamber benefits with single chamber size and longevity.

Your patient's image in the mirror reflects t brand of pacemaker you choose. Choose th new Genisis pacemaker. The thinnest, light DDD yet.

Thinner profile and small size allow for a smaller incision. A smaller pocket. A comf able fit. Although all patients will benefit fr the small size and shape of Genisis, pediatr or thin patients having little subcutaneous ti will especially appreciate its thin, *8 mm* pro and its light, *42 g* weight. Genisis also provi more years of service than thicker, less sophisticated DDD units.*

Choose the newest pacemaker design that m your rigid demands and provides safe, effec pacing with no compromises. Genisis.

* Based on comparable output settings and conditions. Data on

Evaluation of Methods of Measurement and Estimation of Left Ventricular Function After Acute Myocardial Infarction

MICHAEL G. JONES, BA, BARRY W. RAMO, MD, GILBERT L. RAFF, MD, TOMOAKI HINOHARA, MD, and GALEN S. WAGNER, MD

Using multiple gated cardiac blood pool imaging and single-plane ventriculography from cardiac catheterization, 2 independent measures of left ventricular (LV) ejection fraction (EF) were determined in each of 21 patients. Patients were seen 2 to 6 weeks after their first acute myocardial infarction and were free of electrocardiographic evidence of conduction abnormalities and left or right ventricular hypertrophy. Differences between the 2 measures of LVEF were examined and then compared with the extent of myocardial necrosis estimated from the standard 12-lead electrocardiogram using the complete 54-criteria/32-point Selvester QRS scoring system. Regression analysis yielded an r value of 0.81 (SEE = 8.05) for the overall relation between the 2 measures of LVEF. Correlation coefficients of −0.70, −0.66 and −0.72 were obtained for the relations of radionuclide LVEF, catheterization LVEF and the mean of these 2 determinations, respectively, compared with QRS score. A QRS score 4 or less achieved 100% specificity and that of 8 or less 100% sensitivity for predicting an LVEF greater than 40%. Thus, the Selvester QRS scoring system may be of value in identifying patients with or without markedly impaired LVEF. This risk stratification may be important in reaching optimal postinfarction therapeutic decisions.

(Am J Cardiol 1985;56:753–756)

Left ventricular (LV) ejection fraction (EF) is often used as an estimation of LV function and subsequent prognosis after acute myocardial infarction (AMI). Radionuclide and contrast ventriculography are the methods most often used for measuring LVEF and intertechnique correlations have consistently been good in patients without AMI.[1–3] However, comparison of LVEF in the immediate post-AMI period measured by both radionuclide and contrast ventriculography has not been reported. The Selvester QRS scoring system, which is based on the standard 12-lead electrocardiogram (ECG), has been shown to correlate significantly with AMI size,[4–6] and formulas have been developed to describe the relation of QRS score to postinfarction LVEF.[7–13] Some of these studies have used radionuclide angiography[9–12,14] and others, contrast ventriculography[8,15] as their standard for evaluating other techniques. In this study, the Selvester QRS scoring system was applied to each patient's 12-lead ECG. Correlations were made between the 2 methods of LVEF measurement, the QRS score and each of the methods for determining LVEF, and the QRS score and the mean of the 2 LVEF values.

From the Department of Medicine, Duke University Medical Center, Durham, North Carolina, and the Presbyterian Heart Institute, Presbyterian Hospital Center, Albuquerque, New Mexico. This work was supported in part by Research Grant HL-17670 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received March 12, 1985; revised manuscript received May 20, 1985, accepted May 22, 1985.

Address for reprints: Galen S. Wagner, MD, Box 31211, Duke University Medical Center, Durham, North Carolina 27710.

Methods

Study population: Patients were referred for cardiac catheterization 2 to 6 weeks (mean 3.75) after their first AMI, which occurred between July 1982, and March 1984. Infarction was documented by patient history, ECG and enzyme studies; catheterization was performed to evaluate the severity of coronary artery disease and ventricular dysfunction. Patients were required to meet the following inclusion criteria: a standard 12-lead ECG taken 24 to 36 hours before cardiac catheterization; a multiple-gated cardiac blood pool scan performed within 48 hours of catheterization; no associated valvular heart disease; no evidence on ECG of left or right ventricular hypertrophy, left anterior or posterior fascicular block or left or right bundle branch block; and no antiarrhythmic medication for frequent premature ventricular contractions, atrial fibrillation or ventricular tachycardia. Twenty-one patients (19 men, 2 women) met inclusion criteria for this study (Table I). Mean age was 58 years (range 39 to 71).

Gated blood pool study: A multiple-gated blood pool study was performed to measure the radionuclide LVEF within 48 hours of cardiac catheterization in all 21 patients. Sixteen patients had their radionuclide study within 24 hours before catheterization; in the other 5, it was performed within 48 hours after catheterization.

After red blood cell tagging with pyrophosphate, the modified in vitro method was used for the administration of 20 to 24 mCi of technetium-99m sodium pertechnetate. The patient was positioned and imaged for an anterior, best septal (left anterior oblique) and steep left anterior oblique 70° views. Each projection was acquired via computer (ADAC CDS) for 6 minutes in a dynamic 64 × 64 × 8 mode in 16 segments. Areas of interest from end systole, end diastole and an apical background region were determined using an automatic edge-detection program. These areas were visually checked

Ant = anterior; AMI = acute myocardial infarction; Cath = catheterization; Inf = inferior; Lat = lateral; LVEF = left ventricular ejection fraction; RN = radionuclide.

for accuracy, with manual correction if necessary, and a global radionuclide LVEF was determined using the aforementioned program.

Cardiac catheterization: Patients underwent catheterization from either the femoral or brachial artery approach within 36 hours of their admission ECG. Single plane contrast ventriculography was performed to obtain the "catheterization LVEF" before selective coronary angiography. Ventriculography was accomplished in the 30° right anterior oblique position using 40 to 60 ml of contrast medium over 2 to 3 seconds. Tracings of the left ventricle in peak systole and diastole were manually drawn and subsequently digitized to estimate LVEF according to a standard technique.[16] The degree of stenosis in each of the major coronary arteries was visually assessed and a "diseased vessel" was defined as one with 75% or more narrowing.

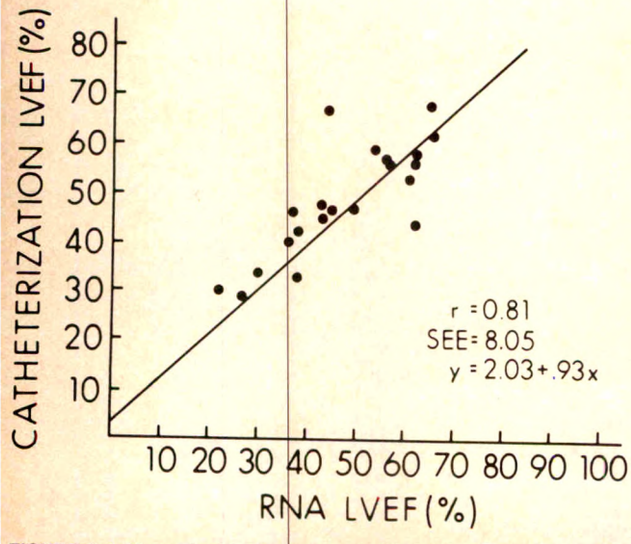

FIGURE 1. Left ventricular ejection fraction (LVEF) correlation between catheterization contrast ventriculography and multiple gated cardiac blood pool imaging (RNA) in 21 patients evaluated 2 to 6 weeks after acute myocardial infarction.

QRS scoring system: A point score was determined from each patient's ECG using the complete 54-criteria/32-point QRS scoring system developed by Selvester et al[17–19] and refined for specificity and application by Hindman et al.[20] ECGs were independently scored by 2 trained observers and discrepancies resolved by conference.

Statistical analysis: Analyses were performed using the Student *t* test, analysis of variance or both. Correlations between LVEF measurements and QRS scores were assessed with linear regression analysis. The mean value of LVEF was determined as ½(radionuclide LVEF + catheterization LVEF). Values were expressed as the mean ± standard deviation. A mean LVEF of more than 40% was selected for assessing specificity and sensitivity of the various levels of QRS score because values of 40% or less are considered indicative of marked impairment of LV function.

Results

Of the 21 patients studied, 10 had inferior AMI, 9 had anterior AMI and 2 had lateral AMI. Four infarcts were subendocardial (non-Q-wave). The mean QRS score was 5.1 ± 4.3 points (range 0 to 13). No significant difference was noted between the number of QRS points scored by patients with anterior AMI (mean 5.5 ± 4.3) vs inferior AMI (mean 5.6 ± 4.4). Table I lists the demographic data for these 21 patients.

Figure 1 displays the regression analysis between radionuclide and catheterization LVEF. Mean LVEF from catherization was 49 ± 12% (range 29 to 68) and 47 ± 13% (range 22 to 66) from radionuclide study; regression analysis yielded an r value of 0.81 (SEE = 8.05) between these parameters. In 13 of the 21 patients (62%) the radionuclide LVEF was less than the catherization LVEF by an average of 5.6%; in 8 patients, radionuclide LVEF averaged 5.8% more than catherization LVEF. In only 5 of the 21 patients was the difference between methods 5% or more.

Figure 2A depicts the relation of QRS score to radionuclide LVEF. The correlation coefficient was −0.70 (SEE = 9.78). The correlation coefficient for catheter-

ization LVEF vs QRS score was −0.66 (SEE = 8.92) (Fig. 2B). Further analysis between the mean value of both measures of LVEF and the QRS score yielded a correlation coefficient of −0.72 (SEE = 8.49). This relation was not significantly different from that of each method considered independently.

Figure 3 depicts the sensitivities and specificities attained by the various levels of QRS scores for identifying patients with a mean LVEF of more than 40%. A QRS score of 4 points or less achieved 100% specificity and that of ≤8 points 100% sensitivity for predicting an LVEF >40%. QRS scores of 5, 6 and 7 were associated with both levels (≤40% and >40%) of LVEF.

Discussion

In this study the relation of the Selvester QRS score to both radionuclide LVEF obtained via multiple gated blood pool imaging and catheterization LVEF obtained via contrast ventriculography was evaluated. The QRS scoring system has been reported in a simplified 37-criteria/29-point version[21] and, recently, in its complete 54-criteria/32-point form.[20] Previous studies have examined the relation of the simplified system to thallium-201 scintigraphy,[9,11] radionuclide left ventriculography[7,9,11,12,14] and clinical, angiographic and prognostic measures.[8,15,22] This study was unique because it examined the relation of the complete version of the scoring system to both radionuclide and catheterization LVEF performed in a group of patients with AMI.

Previous studies examining the relation of radionuclide to catheterization measures of LVEF in non-AMI patients have yielded r values ranging from 0.80 to 0.97 for first-pass techniques,[23] and values as high as 0.93 using computer-generated time-activity curves.[1,3,24] Correlation coefficients have ranged from 0.80 to 0.95 for LVEF comparisons between single plane ventriculography and radionuclide techniques in non-AMI patients.[2,3] No previous study has evaluated this relation in patients immediately after AMI. The correlation coefficient of 0.81 for post-AMI patients in the present study is at the low end of the reported range. However, no systematic difference was noted between the techniques in the measurement of LVEF.

The relation between radionuclide and catheterization LVEF in AMI patients might differ from that for non-AMI patients because the manifestation of and subsequent recovery from AMI varies in individual patients. Dyssynergic or asynergic regions, depending on their location or severity, might distort one measure of LVEF, thus weakening the correlation established in non-AMI patients. Limitations of the techniques used to measure LVEF might under- or overestimate the amount of necrosis responsible for decreased ventricular function. Thus, it was hypothesized that the mean of the 2 techniques would yield a more accurate measure of each patient's true LVEF. However, the regression analysis of mean LVEF vs QRS score showed a relation not significantly different from that when each parameter was considered independently.

Comparison of QRS score to both radionuclide and catheterization LVEF (Fig. 2) yielded correlation coefficients consistent with previously reported values.[7–11,15] Scatter about the low-QRS score end of these regression lines would be expected because of normal compensational variability in hearts with minimal

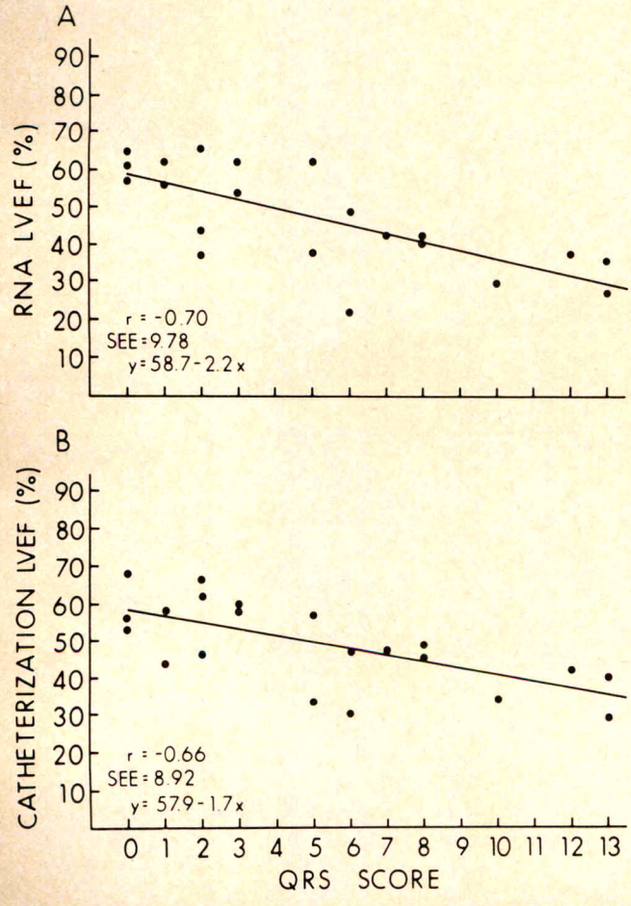

FIGURE 2. Correlations between the QRS score from the 12-lead electrocardiogram and both measures of left ventricular ejection fraction (LVEF). **A,** relation of QRS score and LVEF as determined by multiple gated cardiac blood pool imaging (RNA). **B,** relation of QRS score and LVEF from catheterization single-plane ventriculography.

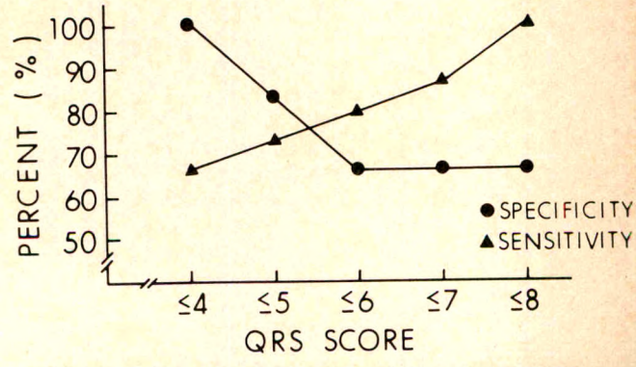

FIGURE 3. Spectrum of specificities and sensitivities per QRS score for indicating patients with a mean left ventricular ejection fraction (½[radionuclide + catheterization]) of more than 40%. Values of specificity and sensitivity are given for each QRS score. The circle corresponding to a QRS score of ≤5 points, for example, represents a specificity of 83%, indicating that 17% of patients (1 of 6) with an LVEF of 40% or less will be falsely included. Similarly, the triangle corresponding to the same score represents a sensitivity of 73%, indicating that 27% of patients (4 of 15) with LVEF of more than 40% will be falsely excluded.

ventricular necrosis. In patients with a low QRS score and depressed ventricular function, some degree of dysfunction may be attributed to residual myocardial ischemia. A study recently completed at this institution,[13] comparing radionuclide LVEF to a QRS score, predicted LVEF in patients before and after coronary artery bypass grafting to identify the cause of depressed LV function. In that study, Hinohara et al conclude that depressed LVEF is due not only to previous AMI, but also to ischemia, which may be reversed by coronary artery bypass surgery. DePace et al[11] have noted that ischemia at rest may limit the usefulness of the ECG to assess LVEF in the individual patient. Thus, in patients with diminished LVEF and a low QRS score, indicative of minimal myocardial necrosis, further intervention may be beneficial in improving ventricular performance and, subsequently, survival after AMI.

Several studies have evaluated the relation between measured LVEF and that estimated by the Selvester QRS scoring system after AMI. Young et al[10] reported that a low QRS score did not reliably predict a normal LVEF in patients with prior AMI; however, they used the simplified version of the scoring system and defined a normal LVEF as ≥50%. Roubin et al,[8] using the simplified system, subsequently determined that a QRS score ≥7 had a specificity of 97% and a sensitivity of 59% for predicting a catheterization LVEF <45%. DePace et al[11] then described a group of 48 patients who were evaluated 2 weeks after AMI; all patients with a QRS score ≤3 had a radionuclide LVEF >40%.

An LVEF of 40% or less is commonly believed to be indicative of marked impairment of LV function and is taken into consideration when reaching decisions regarding prognosis and therapy. Thus, it would be useful to have a quick, inexpensive and readily available method for identifying patients with an LVEF above and below this 40% level. In this study, a QRS score of 4 or less was required to exclude all 6 patients with a mean LVEF of 40% or less (100% specificity), while a score of 8 points or less was required to include all 15 patients with a mean LVEF >40% (100% sensitivity). Thus, it appears the Selvester QRS scoring system is an effective method for identifying patients with or without diminished LVEF after AMI. Because the number of patients in this study was relatively small, these results require validation in future studies.

Acknowledgment: We acknowledge the Presbyterian Heart Institute for financial support of the radionuclide studies. We thank Nancy Hindman and Ken Morris for their helpful comments and suggestions. We appreciate the help of Lynn Moore for her preparation of the patient data forms and Gail McKinnis for preparing the manuscript.

Infections in a Coronary Care Unit

WINSTON A. SCHANDORF, MD, RICHARD B. BROWN, MD, MICHAEL SANDS, MD, and DAVID HOSMER, PhD

All infections in patients in an active coronary care unit (CCU) over a 3-year period were analyzed to ascertain rates, outcomes, pathogens and sites of infections. Standard surveillance methods and definitions of the Center for Disease Control were used. A total of 236 infections were documented in 200 infected patients. Infection rates were 5 and 2% for total and CCU-acquired infections, respectively. CCU infections accounted for 11% of nosocomial infections that occurred within all critical care areas surveyed. Of all documented infections, 131 (56%) were community-acquired and 90 (38%) were acquired within the CCU. Lower respiratory and urinary tract infections were most frequently noted, with *E. coli*, *S. aureus*, and klebsiella-enterobacter-serratia most usually implicated. Mortality among patients with infections was 31%, compared with 8 to 12% in those who were not infected. Those with lower respiratory infections or primary bacteremias had a higher mortality rate than those with infections at other sites ($p < 0.001$). Infections are seen in close to 5% of CCU patients and may adversely affect the survival rate. The mortality rate in infected patients may be 3 times higher than that in the general CCU population. This study also provides data against which other similar institutions can gauge their CCU infection rates.

(Am J Cardiol 1985;56:757–759)

In at least 5% of hospitalized patients within the United States, nosocomial infections develop.[1–5] However, the incidence of nosocomial infection in patients in medical/surgical intensive care units may be significantly greater than this, rates in excess of 20% have been reported.[6,7] Many of these infections are device-related and may be prevented with appropriate infection control measures.[3,8–10]

Studies of infection in the coronary care unit (CCU) are imprecise. A recent statewide study revealed a rate of nosocomial infection of only 1 to 2% within 13 CCUs that were surveyed.[1] However, data collection was incomplete and information concerning pathogens, survivorship and sites of infection was lacking. The present study reviews all infections that occurred in an active CCU during the 3 years between 1982 and 1984 with regard to origin of infection, outcome status, and both the sites and pathogens implicated. This information is important in defining an area for potential reduction of CCU morbidity and mortality and is a yardstick against which other CCUs can gauge their own infection rates for quality assurance purposes.

Methods

The Baystate Medical Center is a 950-bed teaching community hospital associated with the Tufts University School of Medicine. The institution is the second largest hospital in Massachusetts, and admits approximately 40,000 patients yearly for a mean stay of 8 days. Five critical care areas account for 62 beds (7% of total). The CCU contains 16 beds (26% of total critical care beds), all of which are located in private rooms. Criteria for admission to the CCU include documented or suspected mycardial infarction, unstable angina, severe arrhythmias and cardiogenic shock.

The surveillance methods used in our study conformed with those recommended by the Centers for Disease Control.[11] Trained infection control personnel prospectively surveyed all critical care areas on a daily basis and documented infections by using standard surveillance methods. Data recorded included usual demographic characteristics, sites of infection, pathogens implicated and location where the infection was acquired. Infection data were obtained from the patient charts, radiology reports and microbiology results. Infections were defined as community-acquired if infection became clinically manifest before or within 48 hours of hospitalization, as CCU-acquired if they developed more than 48 hours after admission to the CCU or less than 48 hours after CCU discharge, or as other nosocomial if they developed more than 48 hours after hospitalization but not in the CCU.

The following criteria were used for diagnosing infection: (1) Lower respiratory infections were identified by the presence of purulent sputum, fever and cough plus a chest x-ray demonstrating new alveolar infiltrates. (2) Urinary tract infections were identified by significant bacteriuria (more than 10^5 organisms/ml of urine) regardless of symptoms. (3) Wound infections were identified by purulent drainage. (4) Other cutaneous sources (cellulitis, furuncles) were diagnosed by usual clinical criteria. (5) Bacteremias required the documentation of the same organism in at least 2 separate blood cultures. (6) Meningitis required a positive cerebral spinal fluid culture or gram stain. All infected patients were followed up until either death or hospital discharge to determine their clinical outcome status (i.e., lived to hospital discharge, died in CCU or died after CCU discharge). The total number of

admissions was obtained from a logbook maintained in the CCU and was used to determine the denominator data for infection rates.

Information for each infection episode was entered into a computer file for statistical analysis. Because the objective of the study was to analyze data that were nominally scaled, chi-square methods for contingency tables were used. Tables in the study that displayed statistically significant variations were further analyzed using Tukey-Freeman standardized residuals. These residuals were used to locate differences among infections displaying a particular characteristic. The computations were performed using a BMDP statistical computer package.[12] Because the only statistical test used was the chi-square test of homogeneity of proportions, only p values are reported.

Results

During the 3-year study period there was a total of 5,017 CCU admissions. The annual mortality rate among all patients admitted to the CCU during this study period ranged from 8 to 12%. Two hundred thirty-six infections were documented among 200 patients. Table I lists basic characteristics and rates of infection of the CCU compared with other units within the hospital. Infection rates within the CCU were 5 and 2% for total and CCU-acquired infections, respectively. Compared with other intensive care areas, the CCU accounted for 13% of total infections and 11% of those acquired in intensive care units. One hundred thirty-one (56%) total infections were community-acquired and 90 (38%) were acquired within the CCU. Only 15 (6%) were nosocomially acquired but outside of the CCU.

Table II lists organisms found by sites of infection. Infections of the urinary and lower respiratory tracts were most frequently seen and accounted for 51 and 30% of infections, respectively. *E. coli* was the single most frequently encountered pathogen, accounting for 26% of isolates. *S. aureus* and klebsiella-enterobacter-serratia group each accounted for about 11% of isolates. Cultures were not obtained in 6% of the patients, and in about another 6% of the documented infections no pathogens were isolated.

The mortality rate of patients with infections within the CCU was 22%, an additional 9% died after leaving the CCU. Table III lists patient outcome status compared with both acquisition status and site of infection. For those few patients with more than 1 infection, grouping was tabulated by first infection. Acquisition status had little influence on patient outcome. In all groups, more than 60% of infected patients survived to hospital discharge. However, site of infection was statistically correlated with CCU mortality ($p < 0.001$). Patients with both lower respiratory infections and primary bacteremias were more likely to die in the CCU than those with genitourinary infections ($p < 0.001$).

Discussion

The purpose of this observational study was to explore the epidemiology and importance of infections in CCU patients. Only 1 previous investigation has addressed this issue. Wenzel et al,[1] in a statewide surveillance of nosocomial infections, noted a nosocomial infection rate of 1 to 2% among 13 CCUs that were sur-

veyed. However, neither outcome nor acquisition status was addressed, and organisms associated with infections were not studied. A previous study from our institution showed that admission to the CCU comprises approximately 35% of those admitted to all critical care units, but the infections within the CCU comprise only 13% of total infections and 11% of those that are CCU-acquired.[13] That investigation did not specifically address infection-related issues within the CCU itself.

In the present study an overall infection rate of 5% was found. The rate for CCU-acquired infections was about 2%—a rate almost identical to that of the other investigation addressing this issue. However, we could not determine severity of illness or relation of infections to procedures. Our data document that more than 60% of all CCU infections are community-acquired and that 2 to 3% of all patients admitted to the CCU will harbor such infections. Thus, patients admitted to CCU must be evaluated for infection at the time of admission. Almost all of infections originated in either the respiratory or genitourinary tract, and the organisms implicated were those most commonly encountered.

The 22% mortality rate of infected patients while still in the CCU was 2 to 3 times higher than that noted for all CCU patients during the same period. This finding strongly implies that the presence of infection adversely affects patient outcome. The CCU appears to be a less important source of both total and intensive care unit-acquired infection than other critical care areas. However, such infections still occur in almost 5% of patients. An appreciation of these facts may allow better and more rapid assessment of infections, with the potential for decreased morbidity and mortality rates.

CME Test #28

Effect of Intracoronary Thrombolytic Therapy on Exercise-Induced Ischemia After Acute Myocardial Infarction*

The University of Alabama School of Medicine designates this continuing medical education activity for 1 credit hour in Category 1 of the Physician's Recognition Award of the American Medical Association. Answers are to be marked on the instruction sheet on page A113.

1. In patients receiving streptokinase (SK), baseline angiography revealed that the infarct-related coronary artery was completely obstructed in:
   a) 70%
   b) 95%
   c) 75%
   d) 85%

2. In all patients in this study, past intervention angiography showed patency of the infarct-related coronary artery in:
   a) 50%
   b) 86%
   c) 67%
   d) 54%

3. In comparing patients with incomplete and complete coronary obstruction, peak creatine kinase values were:
   a) lower in patients with incomplete obstruction
   b) lower in patients with complete obstruction recanalized
   c) not significantly different
   d) lower in patients with complete obstruction not recanalized

4. The group that had the longest time for creatine kinase value to peak was:
   a) patients with incomplete obstruction
   b) patients with complete obstruction recanalized
   c) patients with complete obstruction not recanalized
   d) a and b above

5. Thallium-201 defect scores at rest were:
   a) increased in the SK group
   b) increased in the control group
   c) increased in both groups
   d) decreased in both groups

6. The exercise-induced thallium-201 defect score was:
   a) lower in patients with opened vessels
   b) higher in patients with closed vessels
   c) independent of the number of diseased coronary vessels in both groups
   d) none of the above

7. Among patients with 1-vessel disease, ejection fraction increase during exercise was:
   a) higher in closed infarct-related arteries
   b) lower in closed infarct-related arteries
   c) not significantly different among the groups
   d) greater than in patients with 2-vessel disease

8. Patients with acute myocardial infarction treated with SK had improvement in perfusion scintigrams in:
   a) 5 or 6 days
   b) 5 or 6 weeks
   c) 3 or 4 weeks
   d) 3 or 4 months

9. Of the patients undergoing follow-up angiography after thrombolysis, reocclusion has been reported to be:
   a) 8 to 26%
   b) 27 to 54%
   c) 45 to 63%
   d) less than 10 to 32%

10. The optimal management course after successful thrombolytic therapy has:
    a) implications for continued SK use
    b) been possible with nitroglycerin patches
    c) not been defined
    d) none of the above

Miles Pharmaceuticals

Innovative Products From Original Research

A number of important new therapeutic agents from Miles Pharmaceuticals are on the horizon. Promising research is underway in the fields of metabolic, infectious, cardiovascular and cerebrovascular disease.

These intense research and development programs reflect the vast increase in resources at Miles Pharmaceuticals in the past seven years, made possible by an association with one of the world's largest pharmaceutical companies.

Together, Miles Pharmaceuticals and its parent company have more than 200 years of ethical drug and medical experience. And, together, they are committed to on-going research that will improve the health of your patients. You'll be hearing more from Miles Pharmaceuticals in the months and years ahead.

Determination of Left Ventricular Mass Using Single-Photon Emission Computed Tomography

CHRISTOPHER L. WOLFE, MD, DONALD E. JANSEN, MD, JAMES R. CORBETT, MD, KIRK LIPSCOMB, MD, GREGORY GABLIANI, MD, NEIL FILIPCHUK, MD, GREGORY REDISH, MD, SAMUEL E. LEWIS, MD, and JAMES T. WILLERSON, MD

To test the hypothesis that single-photon emission computed tomography (SPECT) could actually determine left ventricular LV mass in humans, SPECT measurements of LV mass were compared with LV mass determined by cineangiography in 12 patients with normal coronary arteries and LV function. Repeat SPECT determinations of LV mass were carried out in 5 patients. Projection images of the left ventricle were acquired after intravenous injection of thallium-201 (Tl-201) using a rotating gamma camera. Transverse sections were reconstructed by filtered backprojection. The boundary of LV uptake of Tl-201 in each transverse section was defined using a 3-dimensional threshold detector. Scintigraphic LV mass (total number of voxels demonstrating LV Tl-201 uptake × voxel volume × specific gravity of myocardium) was compared with angiographic LV mass. There was good correlation between LV mass determined by SPECT and that determined by cineangiography. Mean angiographic LV mass was 208 ± 45 g (± standard deviation). Mean SPECT LV mass was 204 ± 42 g. Linear regression analysis revealed the following relation: SPECT LV mass = 0.76 × angiographic LV mass + 46.1 (r = 0.82, root-mean-square deviation from regression = 24.7). The SPECT values of LV mass varied an average of 10.4 ± 4.6% (± standard deviation) in the 5 patients in whom 2 determinations were made. Thus, SPECT of Tl-201 can accurately measure LV mass in humans.

(Am J Cardiol 1985;56:761–764)

The measurement of viable left ventricular (LV) mass may have important prognostic significance in patients with coronary artery disease and cardiac hypertrophy.[1–5] Rackley et al[6] and Kennedy et al,[7] showed that LV mass can be assessed accurately by LV angiography. Recently, several investigators demonstrated that 2-dimensional (2-D) echocardiography is a useful noninvasive means of determining LV mass in selected patients.[8,9] However, this technique makes certain geometric assumptions and is dependent on the quality of the 2-D echocardiogram. Furthermore, this technique does not readily distinguish between viable and nonviable myocardium. Single-photon emission computed tomography (SPECT) is useful as a means of determining viable LV mass in the canine model.[10–11] In this study we tested the hypothesis that SPECT with thallium-201 (Tl-201) may be used to determine LV mass in humans.

Methods

Patients: We compared SPECT and angiographic measurements of LV mass in 12 consecutive patients who were found to have normal coronary arteries and LV function while undergoing diagnostic left ventriculography and coronary angiography for evaluation of chest pain. Six patients had a history of systemic arterial hypertension and 3 had electrocardiographic evidence of LV hypertrophy. No patient had electrocardiographic criteria for right ventricular hypertrophy.

Angiographic technique: Biplane left ventriculography was accomplished by injecting 56 ml of iodinated contrast material (Renografin-76®, Squibb) over 4 seconds through a pigtail catheter located within the mid-left ventricle. The ventriculogram was recorded simultaneously from the 30° right anterior oblique and 60° left anterior oblique projections on 35-mm Kodak® film at 60 frames/s. Coronary angiography was performed after left ventriculography.

Radionuclide technique: All patients were studied at rest and in the fasting state. Each patient was injected with 2.0 to 2.4 mCi of Tl-201 (New England Nuclear) while standing upright, and allowed to ambulate for 5 minutes. Imaging was begun 10 minutes after Tl-201 injection. Thirty-two images containing a minimum of 80,000 counts were acquired over 180° from the 60° right anterior oblique to the 30° left posterior oblique position using a rotation gamma camera (GE 400T, General Electric Medical Products Division). This camera was equipped with a low-energy (200 keV), general-purpose, parallel-hole collimator and interfaced with a dedicated computer (Medical Data Systems). Planar resolution was 15.7 mm full width half maximum at 20 cm using water as the scatter medium. Each image was acquired at a ditigal resolution of 64 × 64. Total acquisition time was about 30 minutes per study. The projection images were corrected for field nonuniformity using a 90-million-count liquid technetium-99m flood[12] and prefiltered using a 5 × 5 center-weighted spatial filter with a frequency cut-off of 0.15. After correcting for center of rotation, transverse sections (Fig. 1), 1 pixel (0.476 cm) thick, were reconstructed by filtered backprojection. Sections displaying LV uptake of Tl-201 were selected by visual inspection. The epicardial and endocardial boundaries of Tl-201 uptake within these transverse sections were defined by applying a simple 3-dimensional threshold detector to the reconstructed images (Fig. 2). This threshold was 50% of the maximal pixel count within the entire ventricle. The threshold was selected by retrospective analysis of the first 2 studies. In each study, the threshold was adjusted until the scintigraphic LV mass equaled the angiographic LV mass.

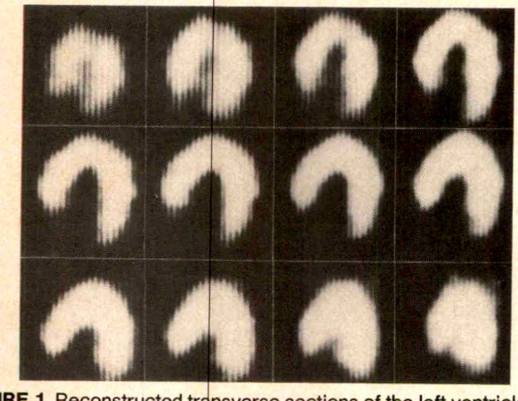

FIGURE 1. Reconstructed transverse sections of the left ventricle from apex (**top left**) to base (**bottom right**).

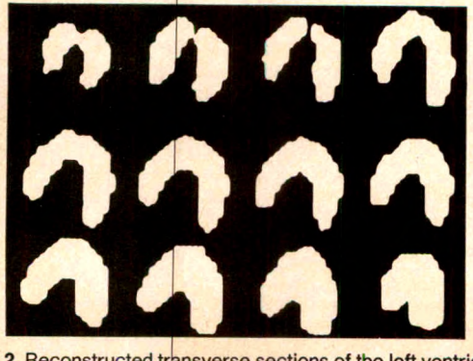

FIGURE 2. Reconstructed transverse sections of the left ventricle after the epicardial and endocardial borders were defined by an automatic 3-dimensional threshold detector. Left ventricular mass was measured from these images.

These 2 empirically derived thresholds were averaged, and this mean threshold value (50% of maximal pixel value/reconstructed volume) was applied prospectively to all studies in a blinded fashion.

In 5 patients, 2 SPECT studies were performed. All SPECT studies were done within 10 weeks of angiography.

Scintigraphic left ventricular mass determination: LV mass was calculated as the total number of volume elements (voxels) demonstrating LV Tl-201 uptake in all sections multiplied by the volume of a single voxel (0.1134 cm^3) and the specific gravity of myocardium (1.05 g/cm^3). Scintigraphic determinations of LV mass were made without knowledge of the value of LV mass calculated by LV angiography. Voxel dimensions were measured using a calibration phantom. All studies were analyzed by 2 independent observers on multiple occasions who were blinded to the results of angiographic determinations of LV mass.

Angiographic left ventricular mass determination: Angiographic determinations of LV mass were made from multiple (3 to 5) end-diastolic frames of a biplane left ventriculogram and averaged. Correction for pin-cushion distortion and calculation of the magnification factor were accomplished using a 3-dimensional coordinate system within the x-ray field as described by Lipscomb.[13] After end-diastolic frames were identified by visual inspection, the endocardial borders were manually traced and digitized on the face of the projector. The thickness of the LV free wall was measured two-thirds of the distance between base and apex. LV mass was then calculated from the following formula, described by Rackley et al[6,7]:

$$\text{LV mass} = \left[4/3\pi\left(\left[\frac{da}{2}+h\right]\times\left[\frac{dl}{2}+h\right]\times\left[\frac{L}{2}h\right]\right)-V\right]1.050$$

where da = transverse diameter from anterior projection, dl = transverse diameter from lateral projection, L = maximal chamber length, and V = volume of the left ventricular chamber.

Statistical methods: The correlation between scintigraphic and angiographic LV mass was obtained with a least squares fit using linear regression analysis.[14] Pearson's r values, calculated from regression analysis, are reported. All mean values are expressed as ± standard deviation. Intra- and interobserver variability are reported as percent variability.

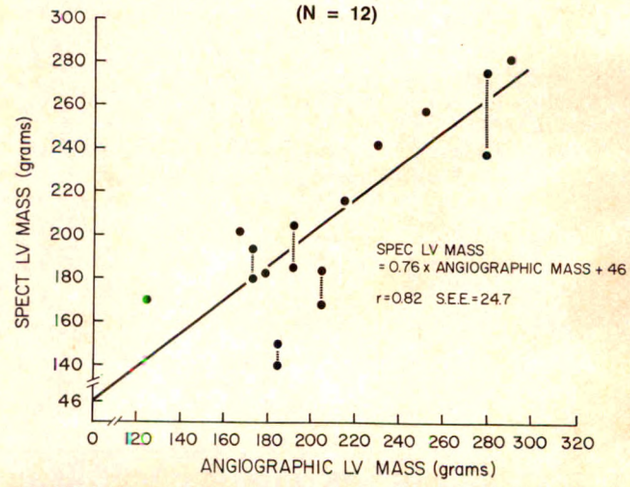

FIGURE 3. Correlation between angiographic and scintigraphic determinations of left ventricular mass. **Vertical dotted lines** connect values of left ventricular (LV) mass measured in 5 patients who had 2 single-photon emission computed tomography (SPECT) studies. S.E.E. = standard error of the estimate.

Results

The correlation between SPECT measurements of LV mass and LV mass determined by cineangiography are shown in Figure 3. Catheterization values of LV mass ranged from 125 to 290 g (mean 208 ± 45 [± standard deviation]). SPECT values of LV mass ranged from 140 to 282 g (mean 204 ± 42). Linear regression analysis revealed the following relation: SPECT LV mass = 0.76 × cath LV mass + 46 (r = 0.82, standard error of the estimate = 24.7 g). SPECT values of LV mass varied an average of 10.4% ± 4.6 in the 5 patients who had 2 SPECT studies. SPECT measurements were reproducible with intraobserver variability of 6% and interobserver variability of 9%. Angiographic determinations of LV mass were reproducible with intra- and interobserver variability of 5%.

Discussion

We[10] and others[11] have shown that SPECT with Tl-201 can accurately quantitate LV mass in the canine model. The present study demonstrates the usefulness of this technique in measuring LV mass in patients. LV mass was calculated from the volume of Tl-201 distribution within the ventricle on reconstructed transverse sections. SPECT LV mass corresponded closely with LV mass determined by ventricular angiography with a Pearson's r value of 0.82 and a standard error of the estimate of 24.7 g.

The fact that SPECT imaging provided good quantitation of LV mass in patients is encouraging when the limitations of this technique are considered. Specifically, image acquisitions were ungated on a system with limited spatial resolution. No correction for attenuation was made. This resulted in blurring of cardiac borders and may account for some overestimation of LV mass. Technical improvements may result in greater resolution and accuracy.

This technique is one of several noninvasive methods that have been used to measure LV mass. Reichek et al[9] reported that 2-D echocardiography, using multiple short-axis images, provides excellent determinations of LV mass. However, this technique is limited by the quality of the images obtainable in a given patient. We obtained 2-D echocardiographic studies in several of the patients described here, but we also found that LV mass was difficult to quantitate in those with chronic obstructive lung disease (COPD) owing to inability to visualize adequately the lateral wall on the short-axis images. In 2 patients with COPD in whom 2-D echocardiographic studies were technically unsatisfactory for quantitation because of lung hyperinflation, 2 of our highest quality SPECT Tl-201 studies were recorded. Pulmonary hyperinflation in patients with COPD may lead to reduced lung attenuation of Tl-201 and result in higher quality SPECT studies. Thus, these techniques may prove complementary in this regard. Peak et al[15] and Iwasaki et al[16] showed that computed tomography can accurately measure LV mass in dogs. Lanzer et al[17] demonstrated that magnetic resonance imaging can accurately quantitate LV mass in vitro in human hearts. All of these techniques have the advantage of better resolution than SPECT. However, further work is necessary to validate these techniques in vivo in humans. The major advantage of SPECT Tl-201 imaging is that it accurately measures perfused LV mass and can differentiate viable from infarcted or ischemic myocardium.

SPECT imaging with Tl-201 to determine LV mass may have important clinical application in patients with ischemic heart disease or marked ventricular hypertrophy. In patients with acute myocardial infarction, the amount of surviving viable myocardium is a major determinant of LV function and prognosis. Because Tl-201 SPECT measures perfused tissue mass, it is ideally suited for assessing the amount of viable LV mass in patients who have had myocardial infarction, and may have an advantage over 2-D echocardiography and computed transmission tomography in this regard. Quantitation of LV mass in patients with cardiac hypertrophy may have important clinical applications as well. In the spontaneously hypertensive rat model, Mirsky et al[18] showed that LV function declines above a certain "critical" LV mass. Linzbach[1,2] suggested that in patients with ventricular hypertrophy, there may be a "critical myocardial weight" above which hypertrophied heart tissue outstrips its blood supply, resulting in a decline in LV function. Furthermore, Gunther and Grossman[19] and Spann et al[20] demonstrated that patients with aortic stenosis who had depressed systolic LV function had significantly more LV hypertrophy than those who presented with normal LV function. Thus, perfused LV mass (or LV mass index) may be a useful prognostic marker in patients with pressure-overload LV hypertrophy and might be useful in the timing of surgical intervention in patients with aortic stenosis.

In conclusion, SPECT of Tl-201 accurately measures LV mass in humans. This technique may find clinical application in patients with coronary artery disease and cardiac hypertrophy.

Analysis of Factors Affecting the Variability of Fick Versus Indicator Dilution Measurements of Cardiac Output

L. DAVID HILLIS, MD, BRIAN G. FIRTH, MD, DPhil, and MICHAEL D. WINNIFORD, MD

This study was performed to assess the relation between Fick and indicator dilution measurements of cardiac output (CO) in a large number of subjects and to evaluate this relation in patients with a low CO, a high CO, and left-sided cardiac regurgitation. In 808 patients (428 men, 380 women, mean age 50 ± 11), CO was measured by Fick and either thermodilution (right atrium to pulmonary artery)(n = 252) or indocyanine green dye ("dye")(pulmonary artery to systemic artery)(n = 556) within 10 minutes of each other. There was excellent agreement between Fick and both thermodilution and dye. The difference between Fick and indicator dilution measurements was 9 ± 9%; it was 10% or less in 67% and 20% or less in 91% of patients. The disparity between Fick and indicator dilution measurements was increased in patients with a low CO (less than 2 liters/min/m^2)(n = 152) (difference 14 ± 11%, p <0.001) and those with aortic or mitral regurgitation (n = 83) (difference 13 ± 11%, p <0.001). In these groups, the disparity between Fick and thermodilution measurements was not exaggerated, but the disparity between Fick and dye measurements was greater. Thus, although there is excellent agreement between Fick and both thermodilution and dye measurements of CO, thermodilution is preferable to dye in patients with a low CO and those with aortic or mitral regurgitation.

(Am J Cardiol 1985;56:764–768)

Although several studies have reported good agreement between the Fick and indocyanine green dye ("dye") methods of measuring cardiac output (CO) in humans,[1–3] none has compared the results of Fick and thermodilution in a large number of patients. It is widely believed that the Fick method is more accurate than indicator dilution in patients with a low CO and, in turn, that the indicator dilution technique is more accurate than Fick in those with a high CO,[4] but no previous report has shown an exaggerated disparity between the Fick and indicator dilution techniques in these persons. Finally, there is disagreement as to whether left-sided regurgitation renders the dye method inaccurate. In these patients with left-sided regurgitation, the first-pass dye curve may be prolonged and, as a result, recirculation begins before the downslope of the primary curve is inscribed.[5] The accuracy of thermodilution in those with left-sided regurgitation has not been assessed. Therefore, the present study was performed to address 2 questions: What is the accuracy of the thermodilution and dye techniques compared with Fick in a very large number of patients? Are the accepted differences between Fick and indicator dilution (thermodilution and dye) exaggerated in patients with a low CO, a high CO, and left-sided regurgitation?

Address for reprints: L. David Hillis, MD, Room L5.134, University of Texas Health Science Center, 5323 Harry Hines Boulevard, Dallas, Texas 75235.

Methods

Patients: From July 1980 to February 1985, CO was measured by both Fick and indicator dilution methods in 808 patients (428 men, 380 women, mean age 50 ± 11 years [± standard deviation], range 18 to 82) referred for cardiac catheterization at Parkland Memorial Hospital, Dallas. All patients gave informed consent. Patients with intracardiac shunting were excluded. Subsequent hemodynamic and cineangiographic evaluation revealed no demonstrable cardiac disease in 146 patients, atherosclerotic coronary artery disease in 399, cardiomyopathy in 68, mitral stenosis in 48, aortic stenosis in 34, primary pulmonary hypertension in 23, constrictive pericarditis in 4, aortic aneurysm in 2, and coarctation of the aorta in 1 patient. Eighty-three patients had cardiac regurgitation: 42 aortic (AR) and 41 mitral (MR); in all cases the regurgitant fraction was more than 0.40 and angiographic grade of regurgitation was 2+, 3+, or 4+.[6]

Measurements of cardiac output: In each patient, catheters were placed in the pulmonary artery and a systemic artery, and CO was measured by the Fick principle. A 3-minute sample of the patient's expired air was collected in a Douglas bag. The patient's nose was firmly clipped shut so that no air could escape through it, after which he or she was asked to hold a special mouthpiece between the lips and to breathe entirely through it. The mouthpiece was attached to the Douglas bag through a 2-way valve with its sidearm open to room air, so that the patient inspired air from the room and expired only into the Douglas bag. Immediately after collection, the contents of the Douglas bag were analyzed by measuring the oxygen content of room air and that of an aliquot of the patient's expired air (with a Beckman oxygen analyzer) and the volume of air in the Douglas bag (with a Tissot spirometer). The oxygen consumption was expressed in milliliters per minute.

The systemic arterial and mixed venous blood samples were drawn into 3-ml heparinized glass syringes, capped, placed on ice, and analyzed immediately with a reflectance oximeter (American Optical). At the same time, a sample of blood was obtained for measurement of hemoglobin concentration. The arteriovenous oxygen difference was calculated as: difference between systemic arterial and mixed venous oxygen saturations × hemoglobin [in g/dl] × 1.39 [ml O_2/g Hgb] × 10 dl/liters. It was expressed as milliliters per liter.

Immediately after Fick determination of CO, CO was measured by thermodilution in 252 patients and by dye in the other 556, according to methods previously described.[7–10] In each patient 3 to 5 measurements were performed and their values averaged. The variability of thermodilution and dye CO values in our laboratory is ±4%. Thus, in all patients, CO was measured in close temporal proximity (within 10 minutes) by Fick as well as by thermodilution (n = 252) or dye (n = 556).

Statistical analyses: In each patient, the CO value by Fick and indicator dilution was divided by the body surface area, yielding the cardiac index. The difference between Fick and indicator dilution CO values was divided by the Fick CO to give the percent difference. Using a Student *t* test,[11] the percent differences in the 252 patients in whom Fick and thermodilution measurements were accomplished were compared with those in the 556 in whom Fick and dye measurements were made. The percentage of patients in whom the Fick and thermal measurements were within 10% and 20% of each other was compared to the percentage in whom Fick and dye measurements were within 10% and 20% of each other using a chi-square analysis.[11,12] These same statistical methods were used to examine the patients in whom the Fick CO was less than 2 liters/min/m^2 (n = 152) or 4 liters/min/m^2 or more (n = 32) as well as those with MR or AR (n = 83). Finally, in both the thermodilution and dye groups, the Fick and indicator dilution cardiac indexes were compared with a 2-variable linear regression analysis.

All data are reported as mean ± standard deviation. For all analyses, a p value <0.05 was considered significant.

Results

For the 808 patients, the Fick COs averaged 2.59 ± 0.68 liters/min/m^2 (range 0.91 to 5.31) and the indicator dilution COs averaged 2.56 ± 0.62 liters/min/m^2 (range 0.96 to 5.38). The 252 patients in whom Fick and thermodilution measurements were performed had an average Fick CO of 2.58 ± 0.60 liters/min/m^2 (range 1.07 to 4.48) and an average thermodilution CO of 2.54 ± 0.54 liters/min/m^2 (range 1.23 to 4.25). The 556 patients in whom CO was measured by Fick and dye methods had an average Fick CO of 2.59 ± 0.73 liters/min/m^2 (range 0.91 to 5.31) and an average dye CO of 2.58 ± 0.70 liters/min/m^2 (range 0.96 to 5.38). The average difference between Fick and indicator dilution COs was 0.23 ± 0.20 liters/min/m^2 (range 0 to 1.39), and the average percentage difference was 9 ± 8% (range 0 to 69%).

Agreement between Fick and indicator dilution techniques: For the 252 patients in whom CO was measured by Fick and thermodilution methods, there was excellent agreement between the 2 techniques ($r = 0.89$, $p < 0.001$, SEE = 0.15 liters/min/m^2). The difference between Fick and thermodilution averaged 8 ± 8%. It was 10% or less in 173 patients (69%) and 20% or less in 234 (93%). For the 556 patients in whom CO was measured by Fick and dye, the correlation between the 2 methods was excellent ($r = 0.91$, $p < 0.001$, SEE = 0.20 liters/min/m^2). The difference between Fick and dye methods averaged 9 ± 9% (difference not significant [NS] compared with the 252 patients in whom CO was measured by Fick and thermodilution methods). The percentage difference was 10% or less in 369 patients (66%) and 20% or less in 499 (90%) (NS compared with patients in whom CO was measured by Fick and thermodilution methods).

Influence of a low cardiac output on the Fick-indicator dilution relation: In 152 patients, the Fick CO value was less than 2 liters/min/m^2. In these patients, the difference between Fick and indicator dilution CO averaged 0.22 ± 0.17 liters/min/m^2, and the difference was 14 ± 11%. The difference between Fick and indicator dilution was 10% or less in only 73 patients (48%) and 20% or less in only 117 (77%) (Table I). The Fick CO value exceeded the indicator dilution CO value by more than 0.05 liters/min/m^2 in 103 patients, (68%), whereas the opposite occurred in only 25 (16%) ($p < 0.001$)(Table II).

Of the 624 patients with a Fick CO of 2.00 to 3.99 liters/min/m^2, the absolute difference between Fick and indicator dilution CO was 0.22 ± 0.20 liters/min/m^2 (NS compared with the 152 patients with a CO of less than 2 liters/min/m^2), but the difference was 8 ± 7% ($p < 0.001$ compared with the 152 with a CO of less than 2 liters/min/m^2). In 72% the difference between Fick and indicator dilution was 10% or less and in 94% it was 20% or less, both significantly greater than the values for the

Fick CO > indicator dilution CO by >0.05 liters/min/m²	7
Fick and indicator dilution COs within 0.05 liters/min/m²	0
Fick CO < indicator dilution CO by >0.05 liters/min/m²	25†
Aortic or Mitral Regurgitation (n = 83)	
Fick CO >indicator dilution CO by >0.05 liters/min/m²	44
Fick and indicator dilution COs within 0.05 liters/min/m²	20
Fick CO < indicator dilution CO by >0.05 liters/min/m²	29

* p <0.001 compared to the other 2 groups with a CO <2 l/min/m²;
† p <0.001 compared to the other 2 groups with a CO ≥4 l/min/m².

152 patients whose Fick COs were less than 2 liters/min/m² (Table I).

The difference between Fick and thermodilution was 10% or less in 25 of the 39 patients (64%) with a Fick CO of less than 2 liters/min/m², whereas the difference between Fick and dye was 10% or less in only 51 of the 113 patients (45%) with a Fick CO of less than 2 liters/min/m² ($\chi^2 = 4.173$, p = 0.041).

Thus, although the absolute difference between Fick and indicator dilution measurements of CO was not altered by a CO of less than 2 liters/min/m², the percentage difference between them was significantly increased when CO was less than 2 liters/min/m². This was true for dye but not for thermodilution measurements.

Influence of a high cardiac output on the Fick-indicator dilution relation: Of the 808 patients, only 32 had a Fick CO 4 liters/min/m² or more; the difference between Fick and indicator dilution in these patients was 9 ± 6%. In 20 (63%) the difference between Fick and indicator dilution was 10% or less, and in 30 (94%) it was 20% or less (Table III). The indicator dilution CO exceeded the Fick CO by more than 0.05 liters/min/m² in 25 patients (78%), whereas the opposite was true in only 7 (22%) (p <0.001) (Table II).

Of the 624 patients with a CO of 2.00 to 3.99 liters/min/m², the difference between Fick and indicator dilution was 8 ± 7% (NS compared with the 32 with a CO of 4 liters/min/m² or more). In 449 patients (72%), the difference between Fick and indicator dilution was 10% or less and in 586 (94%) it was 20% or less (NS compared with those with a CO of 4 liters/min/m² or more). The relation between Fick and both thermodilution and dye was similar (Table III). Thus, the difference between Fick and indicator dilution methods was not influenced substantially by a CO of 4 liters/min/m² or more.

Influence of aortic or mitral regurgitation on the Fick indicator dilution relation: Eighty-three patients had AR or MR of the severity previously described. For these patients, the absolute difference between Fick and indicator dilution CO averaged 0.32 ± 0.28 liters/min/m², and the percent difference was 13 ± 11%. In contrast, 725 patients had mild or no regurgitation; in these patients, the absolute difference between Fick and indicator dilution was 0.21 ± 0.18 liters/min/m² and the percent difference was 9 ± 8% (both p <0.001 in comparison to the 83 with regurgitation). The difference between Fick and indicator dilution was 10% or less in 41 of the 83 patients (49%) with regurgitation and in 501 of the 725 (69%) without it (p <0.001) (Table IV). The difference between Fick and thermodilution was 10% or less in 11 (73%) of the 15 with regurgitation, whereas the difference between Fick and dye was 10% or less in only 30 of the 68 patients (44%) with regurgitation ($\chi^2 = 4.196$, p = 0.041).

The 83 patients with AR or MR had an average Fick CO of 2.43 ± 0.73 liters/min/m² (range 0.91 to 5.16). Of these, 56 had a CO of 2 liters/min/m² or more, whereas the other 27 had a CO of less than 2 liters/min/m². The increased disparity between Fick and dye in the patients with regurgitation was unrelated to a low (less than 2 liters/min/m²) CO.

In short, the absolute and percentage differences between Fick and indicator dilution measurements of

TABLE III Influence of a High Cardiac Output (CO) on the Fick-Indicator Dilution Relation

	CO ≥4 liters/min/m²	CO 2.00–3.99 liters/min/m²	χ^2	p
	Fick Versus Thermodilution and Dye (n = 32)	(n = 624)

Fick-dye difference ≤20%	51 (75%)	448 (92%)	18.315	<0.001

CO were significantly increased when AR or MR was present. This was true for the dye technique but not for thermodilution.

Discussion

Although numerous techniques have been introduced to measure CO in humans, 2—the Fick principle and the indicator dilution technique—are generally accepted and widely used. Dye has been used extensively, but recently the thermodilution technique has been frequently used in catheterization laboratories and intensive care units. Three reports[1–3] have shown that Fick and dye measurements of CO are within 20 to 25% of each other in 75 to 90% of patients. Our data are in agreement with these reports: Of the 556 patients in whom Fick and dye measurements were performed, the difference between them was 10% or less in 66% and 20% or less in 90% of patients.

Agreement between Fick and thermodilution measurements of cardiac output: Although 3 studies[1–3] compared Fick and dye in hundreds of subjects, the accuracy of the thermodilution method has not been thoroughly assessed. Branthwaite and Bradley[13] showed a good relation between Fick and thermodilution measurements in 17 patients. They injected saline solution of room temperature into the internal jugular vein and measured the change in temperature in the pulmonary artery with a single-thermistor catheter. Ganz et al,[14] using a catheter with 2 thermistors, showed good agreement between thermodilution and dye in 20 patients. Our data, obtained with modern, balloon-tipped thermal catheters in 252 patients, demonstrate excellent agreement between Fick and thermodilution methods ($r = 0.89$, $p < 0.001$; SEE = 0.15 liters/min/m²), and the results of Fick and thermodilution measurements are similar to those of Fick and dye. Thus, compared with Fick, thermodilution and dye are of comparable accuracy.

Influence of a low or high cardiac output on the agreement between Fick and indicator dilution: The Fick method is widely believed to be more accurate than indicator dilution in patients with a low CO and

indicator dilution is believed to be preferable in those with a high CO,[4] but no previous report has shown that the 2 techniques are disparate in these patients. Our data show that the average difference between Fick and indicator dilution is greater in patients with a CO of less than 2 liters/min/m^2 (14 ± 11%, n = 152) compared with those whose COs are 2.00 to 3.99 liters/min/m^2 (8 ± 7%, n = 624, p <0.001). Furthermore, the Fick-indicator dilution difference was 10% or less in only 48% and 20% or less in only 77% of the 152 patients with a CO of less than 2 liters/min/m^2; in contrast, the Fick-indicator dilution difference is 10% or less in 72% and 20% or less in 94% of the 624 patients with a CO of 2.00 to 3.99 liters/min/m^2 (p <0.001)(Table I).

The increased disparity between Fick and indicator dilution in patients with a low CO is true for the dye method but not for thermodilution. In the patient with a low CO, right-sided injection of dye, with sampling from a systemic artery, may produce a first-pass indicator dilution curve that is so prolonged that recirculation begins before the downslope of the primary curve is inscribed. As a result, measurement of CO may be inaccurate. Theoretically this inaccuracy should not occur with thermodilution because it assesses and measures the curve's shape and area after the right-sided injection and sampling of indicator. Our data reveal a difference between thermodilution and dye measurements. Patients with a CO of less than 2 liters/min/m^2 had an increased disparity between Fick and dye, but not between Fick and thermodilution (Table I).

Although Eliasch et al[2] suggested that the difference between Fick and dye values was exaggerated in patients whose COs were more than 9 liters/min, no subsequent study has provided data to support this. In the present study, only 32 patients had a CO of 4 liters/min/m^2 or more. The relation between Fick and indicator dilution in these patients was similar to that in the 624 patients with a CO of 2.00 to 3.99 liters/min/m^2 (Table III). Therefore, our data do not show that the Fick-indicator dilution disparity is influenced by a high CO (4 liters/min/m^2 or more), but the relatively small number of patients with a high CO may have prevented us from assessing this issue definitively.

Influence of aortic or mitral regurgitation on the agreement between Fick and indicator dilution: There is disagreement as to whether left-sided regurgitation renders the indicator dilution technique inaccurate. In patients with severe MR, Rahimtoola and Swan[5] measured CO by injecting dye into the pulmonary artery and sampling its appearance and concentration in a systemic artery; the resultant dye curves underestimated CO by about 20%. These investigators argued that the distortion of the dye curves, with a resultant miscalculation of CO, was caused by recirculation of indicator in the coronary arterial system. Samet et al[15,16] showed that CO could be measured reliably by the right-sided injection and sampling of dye (right atrium to pulmonary artery) even in patients with severe MR or AR. In these patients, the problem imposed by coronary recirculation was alleviated and, as a result, the dye curves were not distorted in shape or area. Our data complement these observations. In those with AR or MR (n = 83), the Fick-indicator dilution percentage difference was exaggerated (13 ± 11%) compared to those without regurgitation (n = 725) (9 ± 8%, p <0.001). However, the disparity between Fick and indicator dilution was present for dye (for which indicator was injected into the pulmonary artery and sampled in a systemic artery), but not for thermodilution (for which indicator was injected into the right atrium and sampled in the pulmonary artery) (Table IV).

Clinical implications: Our data indicate excellent agreement between Fick and both thermodilution and dye measurements of CO. Thermodilution appears to be preferable to dye in patients with a low CO and those with AR or MR. In these patients, the right-sided injection and sampling of "cold" yields a curve less subject to recirculation-induced distortion than the right-sided injection and left-sided sampling of dye.

ONE OF A KIND... IN CHF

Avoid any change in the classic Lasix®-digitalis regimen

BRAND OF furosemide

You've titrated to a precise therapeutic response. Now, unless your patient's condition changes, the regimen shouldn't. Because if it does, the sensitive diuretic/digitalis/electrolyte balance could be upset. And the consequences could be serious.

So, once a patient has been stabilized on Lasix® tablets, it's only logical to specify Lasix® by brand name and prevent generic substitution. That's the only way you can be sure your patient will always receive the same brand of furosemide tablets... exactly the same formulation and manufacturing process, with the same excipients and binders... with every single refill. In fact, 9 out of 10 cardiologists do specify Lasix® by brand name, and 2 out of 3 take the extra step to prevent substitution.[1]

Lasix® is the most thoroughly documented drug in its class, with quality so consistent that almost 8 billion tablets have been manufactured without a single product recall.

Reference: 1. National survey of 2960 physicians, including 1502 cardiologists and other physicians subspecializing in cardiology, conducted by Hoechst-Roussel Pharmaceuticals Incorporated, Somerville, New Jersey. August 1982.

Please see following page for brief summary of full prescribing information.

Specify:

LASIX®

BRAND OF FUROSEMIDE 20 mg, 40 mg, 80 mg Tablets

Because there's no substitute for quality

©1985 by Hoechst-Roussel Pharmaceuticals Incorporated

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

PREGNANCY: Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

TOPICS IN HYPERTENSION

Edited by JOHN H. LARAGH, MD

644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $49.00. Available on 30-day approval.

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice. . . and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions by 85 eminent specialists. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

The book is conveniently organized for effective consultation and reading.

All This . . . And Room For More

It's Marquette's New MAC PC

What is it?
It's what we used to put in a room 20 foot square . . . to analyze electrocardiograms. A computer which will acquire all 12 ECG leads simultaneously from your patient, and produce a full analysis of both morphology and rhythm in less than 15 seconds.

But it's only the size of a medical text book, weighs 11 pounds and contains its own battery pack for a full days work.

And a MAC PC writes out tracings in real time, 3, even 6 leads at a time, on one piece of paper, complete with interpretative data ready for your patient's chart.

If you add the modem option, the MAC PC will transmit (via telephone, satellite or cellular phone) your ECGs to one of the 200 Central Marquette ECG Processing Centers throughout North America for overreading and will even receive (reverse transmission) previous tracings on your patient from the central file.

We will be pleased to demonstrate the MAC PC. Call or write . . .

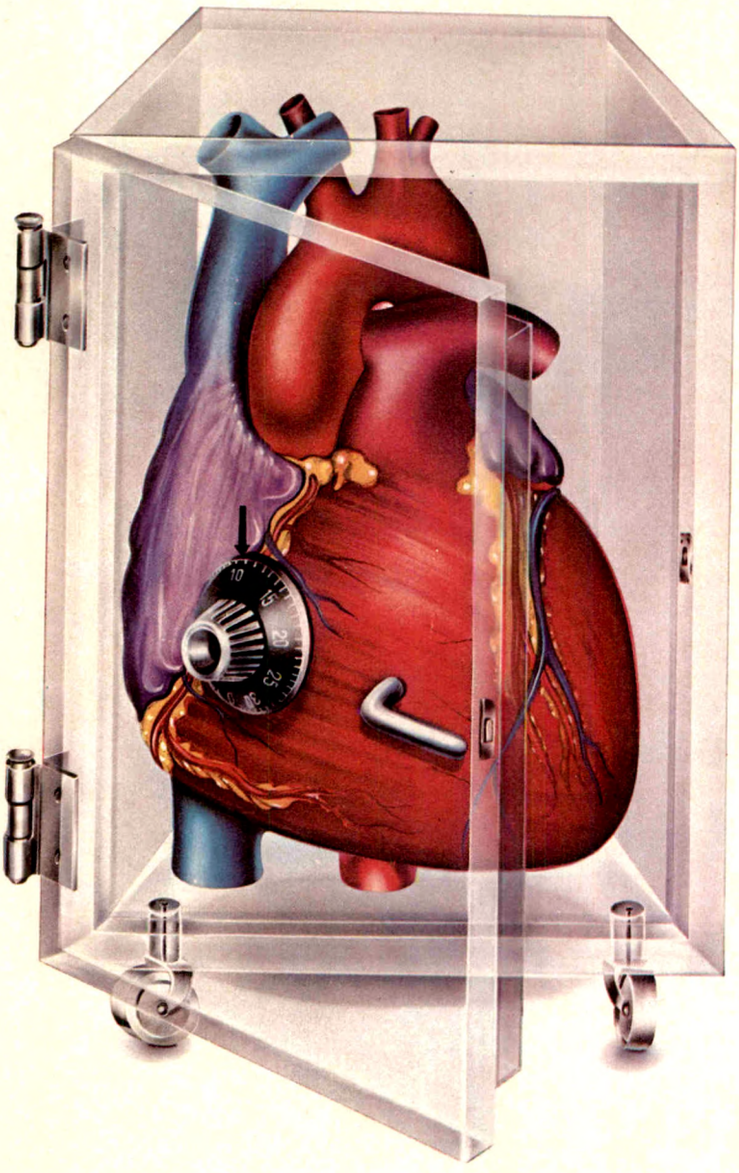
In hypertension...
the risks of some diuretics
or the protection of Lopressor



Safe from complications due to diuretic-induced K+loss

Unlike some diuretics, Lopressor does not waste potassium or cause hypokalemia which has been implicated in cardiac arrhythmias. Some diuretic therapy requires professional monitoring for potassium depletion.

Excellent safety record

Lopressor is generally well tolerated. Shortness of breath and bradycardia have occasionally been reported. Cardioselectivity* offers an added margin of safety compared to nonselective beta blockers.

A safe bet for compliance

The combination of once-a-day dosage and good tolerability makes a Lopressor regimen easy for patients to stay with.

*Exerts a relative preference for beta-one receptors; this preference is not absolute.

Contraindicated in heart block greater than first degree, sinus bradycardia, cardiogenic shock, and overt heart failure. Side effects with Lopressor are generally mild and transient, the most common being tiredness, dizziness, depression, and diarrhea.

Please see next page for Brief Summary of Prescribing Information.

Lopressor®

metoprolol tartrate

Tablets: 50 mg, 100 mg
Ampuls: 5 mg/5 ml
Prefilled Syringes: 5 mg/5 ml

Changing the Course of Cardiovascular Care

Tablets
Ampuls
Prefilled Syringes

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE
Hypertension
Lopressor tablets are indicated for the treatment of hypertension. They may be used alone or in combination with other antihypertensive agents.
Myocardial Infarction
Lopressor ampuls, prefilled syringes and tablets are indicated in the treatment of hemodynamically stable patients with definite or suspected acute myocardial infarction to reduce cardiovascular mortality. Treatment with intravenous Lopressor can be initiated as soon as the patient's clinical condition allows (see **DOSAGE AND ADMINISTRATION, CONTRAINDICATIONS,** and **WARNINGS**). Alternatively, treatment can begin within 3 to 10 days of the acute event (see **DOSAGE AND ADMINISTRATION**).

CONTRAINDICATIONS
Hypertension
Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **WARNINGS**).
Myocardial Infarction
Lopressor is contraindicated in patients with a heart rate < 45 beats/min; significant heart block greater than first degree (P-R interval ≥ 0.24 sec); systolic blood pressure < 100 mmHg; or moderate-to-severe cardiac failure (see **WARNINGS**).

WARNINGS
Hypertension
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and Lopressor slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic. The response should be observed closely. If cardiac failure continues, despite adequate digitalization and diuretic therapy, Lopressor should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice (see **PRECAUTIONS, Information for Patients**).

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly, and the lowest possible dose of Lopressor should be used. In these circumstances it would be prudent initially to administer Lopressor in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See DOSAGE AND ADMINISTRATION.)**

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial; the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Lopressor, like other beta blockers, is a competitive inhibitor of beta-receptor agonists, and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes and Hypoglycemia: Lopressor should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade, which might precipitate a thyroid storm.

Myocardial Infarction
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function, and beta blockade carries the potential hazard of depressing myocardial contractility and precipitating or exacerbating minimal cardiac failure.

During treatment with Lopressor, the hemodynamic status of the patient should be carefully monitored. If heart failure occurs or persists despite appropriate treatment, Lopressor should be discontinued.

Bradycardia: Lopressor produces a decrease in sinus heart rate in most patients; this decrease is greatest among patients with high initial heart rates and least among patients with low initial heart rates. Acute myocardial infarction (particularly inferior infarction) may in itself produce significant lowering of the sinus rate. If the sinus rate decreases to < 40 beats/min, particularly if associated with evidence of lowered cardiac output, atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, Lopressor should be discontinued, and cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

AV Block: Lopressor slows AV conduction and may produce significant first- (P-R interval ≥0.26 sec), second-, or third-degree heart block. Acute myocardial infarction also produces heart block.

If heart block occurs, Lopressor should be discontinued and atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

Hypotension: If hypotension (systolic blood pressure ≤ 90 mmHg) occurs, Lopressor should be discontinued, and the hemodynamic status of the patient and the extent of myocardial damage carefully assessed. Invasive monitoring of central venous, pulmonary capillary wedge, and arterial pressures may be required. Appropriate therapy with fluids, positive inotropic agents, balloon counterpulsation, or other treatment modalities should be instituted. If hypotension is associated with sinus bradycardia or AV block, treatment should be directed at reversing these (see above).

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, Lopressor may be used with extreme caution in patients with bronchospastic disease. Because it is unknown to what extent beta$_2$-stimulating agents may exacerbate myocardial ischemia and the extent of infarction, these agents should *not* be used prophylactically. If bronchospasm not related to congestive heart failure occurs, Lopressor should be discontinued. A theophylline derivative or a beta$_2$ agonist may be administered cautiously, depending on the clinical condition of the patient. Both theophylline derivatives and beta$_2$ agonists may produce serious cardiac arrhythmias.**

PRECAUTIONS
General
Lopressor should be used with caution in patients with impaired hepatic function.
Information for Patients
Patients should be advised to take Lopressor regularly and continuously, as directed, with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Lopressor without consulting the physician.

Patients should know how they react to this medicine before they operate automobiles and machinery or engage in other tasks requiring alertness. Patients should contact the physician if any difficulty in breathing occurs, and before surgery of any type, the patient should inform the physician or dentist that he or she is taking Lopressor.
Laboratory Tests
Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.
Drug Interactions
Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.
Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a 1-year study in dogs, there was no evidence of drug-induced toxicity at or below oral dosages of 105 mg/kg per day. In 2-year studies in rats at three oral dosage levels of up to 800 mg/kg per day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dosage levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.
Pregnancy Category B
Reproduction studies have been performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg and have revealed no evidence of impaired fertility or teratogenicity due to Lopressor. Increased postimplantation loss and decreased neonatal survival did occur in the rats (threshold between 50 and 500 mg/kg), and distribution studies in mice confirm exposure of the fetus when Lopressor is administered to the pregnant animal. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers
Lopressor is excreted in breast milk in very small quantity. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Lopressor is administered to a nursing woman.
Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Hypertension
Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression has been reported in about 5 of 100 patients. Mental confusion and short-term memory loss have been reported. Headache, nightmares, and insomnia have also been reported, but a drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations; and congestive heart failure have been reported. (See **CONTRAINDICATIONS, WARNINGS,** and **PRECAUTIONS**.)

Respiratory: Wheezing (bronchospasm) has been reported in fewer than 1 of 100 patients (see **WARNINGS**).

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100, or fewer, patients.

Hypersensitive Reactions: Pruritus has occurred in fewer than 1 of 100 patients. Rash has been reported.

Miscellaneous: Peyronie's disease has been reported in fewer than 1 of 100,000 patients. Alopecia has been reported.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor.
Myocardial Infarction
Central Nervous System: Tiredness has been reported in about 1 of 100 patients. Vertigo, sleep disturbances, hallucinations, headache, dizziness, visual disturbances, confusion, and reduced libido have also been reported, but a drug relationship is not clear.

Cardiovascular: In the randomized comparison of Lopressor and placebo described in the **CLINICAL PHARMACOLOGY** section, the following adverse reactions were reported:

	Lopressor	*Placebo*
Hypotension (systolic BP < 90 mmHg)	27.4%	23.2%
Bradycardia (heart rate < 40 beats/min)	15.9%	6.7%
Second- or third-degree heart block	4.7%	4.7%
First-degree heart block (P-R ≥ 0.26 sec)	5.3%	1.9%
Heart failure	27.5%	29.6%

Respiratory: Dyspnea of pulmonary origin has been reported in fewer than 1 of 100 patients.

Gastrointestinal: Nausea and abdominal pain have been reported in fewer than 1 of 100 patients.

Dermatologic: Rash and worsened psoriasis have been reported, but a drug relationship is not clear.

Miscellaneous: Unstable diabetes and claudication have been reported, but a drug relationship is not clear.
Potential Adverse Reactions
A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Lopressor.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

Effect of Damped Sine-Wave Shocks on Catheter Dielectric Strength

GUST H. BARDY, MD, FERNANDO COLTORTI, MD, TOM D. IVEY, MD, DAN YERKOVICH, and H. LEON GREENE, MD

This study evaluated the ability of 24 new standard tripolar and quadripolar U.S. Catheter Instruments catheters to withstand a single damped sinusoidal shock delivered by a standard defibrillator. The schema for energy delivery was meant to simulate possible clinical practices. Delivered peak voltage and current were measured during each shock. Each electrode was examined for pitting and changes in line resistance as a consequence of the shock. Electrode pitting occurred on all selected anodal poles. However, it also was found on "unsolicited" electrodes from 7 catheters, indicating that current had followed unanticipated routes. Electrode line resistance was unmeasurable in 6 of these 7 inappropriately pitted electrodes.

Delivered peak voltage and postshock catheter dielectric strength depended on the manner of energy delivery. To simulate a posterior septal accessory pathway ablation procedure, a shock was delivered to 2 proximal (anodal) poles in 16 quadripolar catheters (8 received 200 J and 8 received 360 J). Delivered peak voltage was 3,125 ± 362 V for the 200-J shock and 4,100 ± 160 V for the 360-J shock. Postshock catheter dielectric strength for the 200- and 360-J shock was 1,425 ± 826 V and 601 ± 707 V, respectively. This was significantly lower than peak delivered voltage ($p < 0.001$ for either energy).

To simulate His bundle or ventricular tachycardia focus ablation, 8 tripolar catheters each received a single 200-J shock to the tip electrode. This resulted in a delivered peak voltage of 2,900 ± 351 V, compared with a postshock dielectric strength of 1,325 ± 1,320 V ($p < 0.002$).

It is concluded that standard catheters cannot control current flow adequately during a single high-energy shock because of inadequate dielectric strength. After the first shock an already inadequate dielectric strength deteriorates and increases the likelihood of current leakage with each subsequent shock.

(Am J Cardiol 1985;56:769–772)

Standard electrode catheters may have significant limitations when subjected to high-energy defibrillator shocks for ablation of cardiac tissue. For example, some catheters can develop open circuits or visible changes in insulation after multiple defibrillator shocks.[1] These observations led us to question the likelihood of developing serious nonvisible defects in commonly used, commercially available catheters during and after a single defibrillator shock. The results have implications for the safety of procedures that deliver high energies to standard catheters for ablation of atrioventricular (AV) nodes, accessory pathways and ventricular tachycardia foci.

Methods

Twenty-four U.S. Catheter Instruments (USCI) standard 6Fr recording and pacing catheters (16 quadripolar and 8 tripolar) with interelectrode spacing of 1.0 cm were studied. Each catheter was new and had never been used for any purpose before testing other than visual inspection and measurement of line resistance.

Each catheter was positioned in the right atrium or coronary sinus of a dog by way of a femoral or jugular vein. A single 200- or 360-J damped sinusoidal discharge was delivered to each catheter by a standard Physio-Control Life-Pak 6 using techniques described previously.[1–11] The catheter was connected to the positive output (anode) of the defibrillator. An 8.5-cm disc positioned on the chest was used as the negative pole (cathode). Anode-cathode configuration differed for the quadripolar and tripolar catheters. For quadripolar catheters, 2 adjacent proximal poles were connected in parallel as the anode, as might be done for accessory pathway ablation through the coronary sinus. For tripolar catheters, the distal pole was used as the anode, as might be done during AV node/His bundle or ventricular tachycardia focus ablation. The energy used for quadripolar catheters was either 200 or 360 J (8 catheters were tested with each energy level). All 8 tripolar catheters received 200-J shocks. Both current and voltage waveforms were monitored during delivery of the shock. Current was measured with a Tektronix A6303 current probe. Voltage was measured differentially using a resistive

voltage divider with a 1000:1 input to output ratio (Warren Heggen, University Scientific Instruments Shop) and was displayed simultaneously with the current on a Tektronix #5113A oscilloscope.

After the shock, each catheter was inspected by microscopy for electrode pitting (i.e., melting of the electrode surface) and line resistance was measured for each pole. Catheter dielectric strength was determined with a variable output potential generator that subjected the electrodes to a gradually increasing voltage (Hipotronics). The voltage at which current leakage occurred through the insulation separating the anodal electrodes from other catheter electrodes was catheter dielectric strength. Dielectric strength could be measured meaningfully only once per catheter, because leakage of current through insulation resulted in progressive deterioration in insulation properties.

Catheter dielectric strength subsequently was correlated with peak shock voltage. Dielectric strength of shocked catheters also was compared with the dielectric strength of 5 new unshocked quadripolar catheters.

Statistical comparisons of peak-delivered voltages and dielectric strength were performed with paired *t* tests.

Results

The data are summarized in Table I. Of the 24 catheters studied, pitting was observed on the electrode receiving the shock in each instance. However, on 7 catheters (4 quadripolar and 3 tripolar), pitting was observed on poles *not* intended to have received a shock. This finding indicates inappropriate current discharge to electrodes not intentionally serving as part of the anode. An example is shown in Figure 1, in which pole 2 of a quadripolar catheter is unexpectedly pitted after a 360-J shock to anodal poles 3 and 4.

Catheter line resistance of the distal electrode for either the quadripolar or tripolar catheters was unaffected by the shock (2.0 ± 0.1 ohms before and 2.0 ± 0.1 ohms after). However, the more proximal poles did develop changes in line resistance after the shock. Before the shock, the more proximal poles had a line resistance of 3.3 ± 0.1 ohms. After the shock, it either was unchanged (3.3 ± 0.1 ohms in 18 catheters) or it was open ("infinite" resistance in 6 catheters).

Delivered peak voltage and current during the 200-J quadripolar catheter shocks were 3,125 ± 362 V and 22 ± 5 A, respectively. In comparison, the mean dielectric strength of these catheters after the 200-J shock was 1,425 ± 826 V. Peak delivered voltage was significantly higher than dielectric strength ($p < 0.001$). For the 360-J quadripolar catheter shocks, peak voltage and current were 4,100 ± 160 V and 30 ± 3 A. Postshock dielectric strength was 601 ± 707 V ($p < 0.001$). For the 200-J tripolar catheter shocks, the peak voltage and current were 2,900 ± 351 V and 31 ± 10 A. The dielectric strength for the 200-J shocks to the tripolar catheter was 1,325 ± 1,320 V ($p < 0.002$).

The 5 new quadripolar catheters not subjected to defibrillator shocks had dielectric strengths between

2,200 and 3,500 V (2,780 ± 517). In contrast, dielectric strength of shocked catheters generally was much lower (see before) and varied between 70 and 3,500 V (Table I). The difference in dielectric strength between shocked and unshocked quadripolar catheters was significant at the $p < 0.001$ level.

Discussion

Previous work assessing integrity of standard pacing and recording catheters subjected to defibrillator shocks was done after multiple discharges.[1] The study included visual inspection of catheters and measurement of line resistance of each electrode before and after shocking. Several catheter brands were incapable of sustaining multiple high-energy shocks either by demonstrating increases in line resistance or by showing gross visible deterioration in the insulation. Our work expands on these observations by evaluating both catheter structure and dielectric strength during and after a single damped sinusoidal shock.

None of our catheters that received single shocks had visible defects in insulation and only 6 had changes in line resistance. Each of these 6 catheters also demonstrated inappropriate electrode pitting and deterioration of dielectric strength (1,000 V or less in these 6 catheters). The open circuits indicate marked changes in catheter structure that likely correspond to fusion of the weld between ring electrode and cable.

In 18 catheters line resistance was unchanged. However, this finding alone did not predict whether a catheter's insulation was sufficient to prevent current leaks during defibrillation shocks. Thirteen of these 18 catheters had a dielectric strength less than 2,200 V after the shock—levels inadequate to prevent current leakage for subsequent high-energy shocks. Intact line resistance, therefore, does not guarantee that the catheter insulation is unchanged.
